After removal of the fluid, a tumor of somewhat large dimensions was detected occupying the left side of the abdomen in its lower portion. On account of the patient's condition, no examination was made for the purpose of deciding its character. After the attack of peritonitis the patient enjoyed fair health, being able to perform light household duties and take exercise in the open air. A few days before her death she became quite prostrated, and died presenting some of the symptoms of uræmic poisoning. Her physician, Dr. Wells, stated that the secretion of urine gradually diminished, ceasing almost entirely twenty-four hours before death.

December 31, 1872.—Autopsy by Dr. Mears, assisted by Dr. Wells. Examination limited to abdominal cavity. The abdomen was uniformly distended, and about the same size as in the eighth month of pregnancy. Over the position of the tumor on the left side fluctuation was present, but indistinct and limited by the median line. On the right side fluctuation was more distinct, and was also limited by the median line.

On cutting through the linea alba, the knife divided a portion of intestine, which was found on examination to be the ascending portion of the colon, sealed to the under surface of the abdominal wall by extremely thick and dense layers of adventitious tissue. It passed obliquely across the cavity in a direction from the inguinal region to the umbilicus; its outline could not be detected on the under surface of the wall, so uniformly thick were the layers of the adventitious tissue. Corresponding to a line drawn from a point just below the umbilicus outwards, this adventitious membrane was reflected from the anterior to the posterior wall of the abdominal cavity, forming a distinct septum or false diaphragm; thus enclosing a space which was bounded on the left by the large cyst occupying the left side of the abdomen, above by this septum, and in the other directions by the abdominal and pelvic walls. This cavity contained four pints of turbid fluid with flakes of lymph floating in it. Above this septum the intestines were found pushed up in contact with the stomach. There were no signs of inflammation beyond this septum. The serous coat of the intestines was smooth and glistening, and the intestines were freely movable upon each other. The stomach, spleen, and liver were normal, and free from inflammatory adhesions. The kidneys were about one-third the normal size; their pelves appeared largely dilated, owing to absorption of the greater portion of the medullary substance of the organ. The upper portion of the ureters was dilated; the ureters were firmly pressed upon by the large cyst in their course to the bladder. This organ was empty.

Both ovaries had undergone cystic degeneration; the left was very large, multilocular in character, and firmly bound down in both abdominal and pelvic cavities by strong, dense adhesions. The right was about the size of a large orange, and was, like the left, attached to the uterus by broad and dense pedicles.

In presenting the specimens, Dr. Mears desired to call the attention of the members of the Society to points which he regarded of interest. First, in reference to the fact that paracentesis was performed during an attack of acute peritonitis, which was found by post-mortem examination to have been distinctly circumscribed and limited by the false diaphragm. In considering this subject, the question suggests itself as to the effect exerted, for good or bad, by the tapping. Did it in any way modify the morbid condition? At first sight he was inclined to regard the condition of the kidneys as due to the obstruction produced in the ureters by the large cystic tumor of the left ovary, which was so firmly fastened by adhesions. He had not submitted them to microscopic examination, and could not state whether there were any evidences of structural disease.

In the case of the right ovary he was induced to believe that it presented an instance of cystic disease, developed subsequently to the attack of peritonitis, and caused by the inflammation which interfered with and prevented the proper performance of the function of the ovary,—producing an inflammatory thickening of the capsule, which, as Rindfleisch states, was able to resist the forces which cause a rupture in the normal condition of the capsule and in this way set the follicle free. The accumulation of fluid in the follicle may lead to the formation of a cyst.

Dr. J. V. INGHAM asked Dr. Mears on what grounds he based his statement that the disease in the right ovary did not exist prior to May last. He thought the circumstance that menstruation ceased at that time was scarcely a sufficient reason in the face of the fact that menstruation sometimes continues after both ovaries have been removed. Dr. Ingham thought, too, that the amount of disorganization in the right ovary was too great to permit him to believe that it had existed only since May.

Dr. MEARS replied that his statement was based only on the circumstance of the cessation of menstruation.

Dr. INGHAM said he had asked the question on account of the light which he thought might possibly be shed upon the absence of menstruation in cases of parametritis in which the ovaries seem not to have been involved. This might have been the case here. He did not know how to explain the matter, except that the pressure produced a change in the circulation, which did not respond to the menstrual nisus. That the ovaries alone are responsible for menstruation he thought doubtful.

Dr. JAMES TYSON desired to know what symptoms of uræmia were present; since, if the view of Harley, Roberts, and others, as to a difference in the phenomena of blood-poisoning as produced by deficient elimination of urea, and as due to reabsorption of the urea or the products of its further decomposition, is correct, this is a case in which, in consequence of obstruction to the passage of urine into the bladder, we would expect the symptoms of "ammonæmia," so called, rather than of uræmia, *i.e.*, those of a gradual exhaustion without coma or convulsions.

Dr. MEARS replied that so far as he was familiar with them, the symptoms were more like those of "ammonæmia:" at least there was neither coma nor convulsions while the patient gradually sank into death.

The PRESIDENT asked whether there was not evidence of a diseased state of the kidney apart from the dilatation of the pelvis.

Dr. BERTOLET thought there was diminished extent of the cortical substance, a condition which indeed made the pelvis appear larger than it actually was. He also thought, judging from the leathery hardness of the entire organ and the contracted condition of the cortical portion, that, upon microscopic examination, the amount of connective tissue between the tubules would be found abnormally developed.

The specimen was referred to the Committee on Morbid Growths, who reported that—

"The kidney accompanying Dr. Mears's ovarian cysts was found upon microscopical examination to present, in addition to the slight dilatation of its pelvis, marks of chronic interstitial nephritis; the glomeruli and the tunica propria being very much thickened. The reduction of the cortical substance to less than half its ordinary width, together with the marked retraction of the papillæ and columnæ Bertini, must be regarded as the principal factors in the production of the pelvic enlargement, although the ureter may have been compressed, and no doubt was rendered almost completely impervious."

Dr. R. M. BERTOLET presented the following specimens: *cysto-sarcoma proliferum of the mammary gland* with metastasis in the liver and spleen; *cystic degeneration of the ovaries; eversion of the Morgagnian ventricles.*

This interesting group of specimens was obtained from the body of a greyhound. The tumor, about the size of a man's fist, was situated in the lower mammary gland of the left iliac region. The skin is tensely stretched over the uneven nodulated tumor, which has slowly increased in size since its first appearance a little over a year ago. Externally to the nipple there is a

small fistulous opening leading into the centre of the growth; from it more or less pus and blood was constantly discharged.

Upon section, the tumor is seen to be made up of an aggregation of numerous cysts of very variable size, from that of a small pea up to that of an English walnut. Some of the cysts are filled with a dark-red or black substance of a gelatinous consistence; but the majority of the cavities are more or less completely filled with firm, flesh-like masses of granulations springing from the walls of the cysts. The latter constitute the proliferating sarcomatous growth, while the cyst-walls themselves are probably formed by dilatation of the lacteal ducts and sinuses, since in some of the smaller cysts traces of an epithelial lining can still be detected.

Microscopically the tissue of the tumor is of a very variable character, which the great diversity in both color and consistence would naturally lead one to expect. Certain portions, having a dense, whitish, almost fibrous structure, might in themselves be taken for fibromata; other portions of the growth have a soft, medullary appearance. But it is the latter portion, composed entirely of a cellular and vascular structure, that designates the sarcomatous character. Its cells are round, and contain a nucleus and nucleolus. The protoplasm of the cells is cloudy and finely granular; intercellular substance scant; the blood-vessels coursing in it wide and numerous. If a thin preparation is carefully pencilled out under water, there is seen a very fine network of connective-tissue fibres, in the meshes of which were seated the above-described small round cells. In addition to these round cells, in a few preparations short spindle-cells were noticeable, but in very limited number. The lymph-glands of the groin, and elsewhere, were not enlarged.

The metastatic deposits thickly strewn over the surface of the liver were of small size; the largest was not as large as a pea. In the spleen only a single deposit occurred, but that was as large as a hazel-nut. The histological characters are like those seen in the primary growths, namely, small round cells with interstitial substance, the latter, however, homogeneous in appearance.

The lungs and heart were healthy; but we have an explanation of the marked dyspnœa and muffled bark that existed towards the close of life in the everted condition of the mucous membrane lining the Morgagnian ventricles, which are seen projecting over the free edges of the vocal cords into the glottic fissure. Both of these sacs are filled with a thin translucent fluid; light being freely transmitted through their attenuated mucous covering. The vocal cords and remaining parts of the larynx are in a healthy condition.

The animal has never been pregnant, yet we find cystic degeneration of both ovaries. Each cyst is about the size of a hickory-nut, and filled with a straw-colored fluid.

In the left cornu of the bifid uterus, about one inch from its free end, is seen another distention, as large as a hen's egg. This is made up of an aggregation of smaller cysts; in other words, it is multilocular, and no doubt corresponds to, and was produced by causes similar to those that give rise to, Fallopian cysts in the human subject. The tube leading from the small ovarian cyst to the larger multilocular cyst was rotated a number of times upon its axis; but that part of the tube or cornu which extended to the main body of the uterus was not observed to be twisted when dissected out.

MEDICAL SCHOOL AT GENEVA.—The Conseil-Général of Geneva, Switzerland, has voted to establish a faculty of medicine in that city.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

A SPECIAL meeting of this Society was held January 14, 1873, the President, DR. A. VAN DERVEER, in the chair.

The PRESIDENT announced the death of Dr. J. P. Whitbeck, of West Troy, in some appropriate remarks. Tributes of respect were also paid to the deceased by Drs. R. H. Sabin, Craig, Moore, W. H. Bailey, H. March, and James S. Bailey.

The regular semi-monthly meeting was held January 22, the President in the chair.

Resolutions were offered by Dr. JAMES S. BAILEY, and adopted, in regard to the death of Dr. JOHN F. CROUNSE.

Dr. WILLIAM HAILES addressed the Society on the subject of the anatomy of necrosis in the connective and muscular tissues, illustrating his remarks by means of the stereopticon.

Dr. E. H. DAVIS read a paper on *pleuritic effusion treated by paracentesis*. After introductory remarks, he said: If there is any doubt as to the nature of the case after having examined the patient in the ordinary manner, we can in most cases, with perfect safety, make use of the exploring-needle to correct or confirm the diagnosis.

Having determined the existence of fluid in the pleural sac, questions arise how, when, and where shall we operate for its evacuation.

If the effusion be serous or sero-albuminous, a reasonable hope may be indulged that by suitable treatment it will, under favorable circumstances, be absorbed, however large the quantity. But if the pleura contain pus, constituting empyema, the hope of absorption is greatly diminished, if not entirely precluded.

Therapeutic agents, as purgatives, iodine, mercury, etc., have but little influence in promoting the absorption of pus, and, if such were possible, its influence might result disastrously.

When paracentesis thoracis becomes necessary, it should be resorted to without delay. The place selected for the opening should be where we are sure there is fluid, and where it can be most readily reached.

Miller, in his Surgery, directs us carefully to avoid the margins of the ribs, but in the cases I have operated upon I have selected the upper margin. In some cases I have used the bistoury, in others the trochar. When there is little or no bulging of the intercostal spaces, or when there is the least doubt as to what may be underneath, I should greatly prefer the bistoury, so as to make an open wound and penetrate the cavity of the chest no farther than to divide the pleura. In other cases, after dividing the integuments the trochar is all that is necessary, and is the most convenient.

Dr. Davis reported the following cases as having been operated upon by himself:

Case I.—J. K., æt. 17, mechanic, in June, while boating on the canal, was attacked with pleuro-pneumonia. In ten days from the attack he was brought home, and I was called to attend him.

He was still laboring under inflammatory action, which continued as many more days, and then began to subside and gave encouragement of recovery; but after a few weeks' continuance of it in the subacute form he began to exhibit symptoms of purulent effusion in the left pleural cavity, which gradually increased, when an operation became necessary for its removal. Previous to the operation the left side of the chest was greatly distended, widening the intercostal spaces over that side from the sternum to the spine, and without my being able to discover the respiratory murmur. There was dyspnœa with frequent cough, with but little ex-

pectoration. The appetite and digestion were greatly impaired, with rapidly increasing emaciation.

Before operating, he was placed in a chair, with his arm resting upon its back. The integuments were divided by a puncture from within outwards, about four inches to the left of the spine, and over the lower margin of the eighth rib. The integuments were then pressed upwards with the fingers of the left hand, and a trochar was passed close to the upper margin of the rib, and ten pints of pus were drawn off; as he became faint, the discharge was stopped with a tent, and the wound was dressed with adhesive plaster and a binder. The next day five pints more were taken, and as much more the day following, which emptied the pleural cavity. The tent was then removed daily, and the accumulating pus allowed to escape. The amount of discharge for the first ten days was estimated at thirty-two pints. His appetite now improved, and he partook of a large quantity of food, and digested it well.

For the next three months he continued to improve, but during the fourth month his strength began to fail, and he died by its completion.

No post-mortem allowed.

The points of interest in this case are, first, the large amount of pus discharged; second, the length of time he was able to sustain this great drain upon his system.

Case II.—G. P., captain of a canal-boat, æt. 33, of strong and vigorous constitution, was taken sick while on a trip to this city. Upon his return I was called to see him, and found him suffering with severe inflammation of the right lung, involving the pleura and already threatening suppuration. His previous treatment had been entirely inadequate to his disease and habit of body.

In a little over a month from the time he came under my charge there was evidence of pus in the right pleural cavity, and, believing that nothing could be gained by delay, I determined to evacuate at once while he had strength. I incised cautiously close to the upper margin of the sixth rib, and drew off five pints of pus, when a tent was inserted and the wound dressed with adhesive plaster and bandage. This was removed daily, and the discharge continued in gradually diminishing quantity for about three months, when it ceased, and the wound healed. At this time his cough was severe and he expectorated pus freely. If at any time he lay upon his right side, he could raise little or nothing, but if he then turned upon his left side the flow of pus would occasionally threaten suffocation, and he would expectorate from a gill to a half-pint in a few minutes, showing that the abscess had not only involved the lung but had formed a communication with the bronchi.

From this time he slowly improved until he completely regained his health.

This was at the time of the rebellion; and at the first call of the North for troops he enlisted in the army, and served with credit through the war.

Case III.—W. D., farmer, æt. 30, while ploughing caught a severe cold, which brought on a difficulty of the lungs, from which he never entirely recovered.

In about one year from this attack I was called to see him. He was then laboring under what I regarded as the inflammatory phthisis of Niemeyer. The right lung was to a great extent disorganized, but the left one was still in a condition to perform its functions.

By means of succussion the presence of air in the left pleural cavity was detected.

He was suffering great difficulty of breathing, and inability to lie down, from the feeling of impending suffocation.

I believed his case hopeless, and so expressed myself to him, but he urged me to operate for his relief. He was placed in a chair, and with a bistoury the integuments were divided, and a trochar was passed through the intercostal space close to the upper margin of the rib near the inferior angle of the scapula, and seven pints of pus were drawn off, greatly to his relief. The difficulty in breathing was relieved, and he could now lie down in bed and rest with comfort, which he had not done before in many weeks. He expressed himself as well satisfied with the result, although he died in less than three weeks from the operation.

No post-mortem was allowed.

There are three questions of interest connected with this case. First, did this pus have its origin in a pulmonary abscess which burst into the pleural cavity? Second, are such large accumulations of matter liable to occur in the course of phthisis pulmonalis? Third, did the relief obtained justify the operation at so late a period?

Case IV.—H. B., son of a farmer, æt. 19, was taken sick, and nearly one month later I was called in council with several other physicians. His family physician informed us that he had considered the disease pleurisy, and we fully concurred in his opinion.

We found him lying upon his left side, unable to change his position without great inconvenience, and his countenance expressed great suffering and anxiety. There was no sound of respiration, either morbid or natural, over the whole left lateral region. The side was a little distended, with prominence of the intercostal spaces. By placing the hand over the region of the heart, I marked the distinctness with which I seemed to feel its concussion against the walls of the chest. The stethoscope revealed the organ pulsating near the margin of the right axilla. I believed the case to be one of hydrothorax, and proposed to evacuate the fluid, but, as there was a difference of opinion on the part of a distinguished physician present, it was thought best to delay. In three days more we met again, and, as we were still unable to agree as to the propriety of opening the chest, we explained the difficulty to the patient and his friends, and, as he was rapidly failing, they expressed a desire that an effort to relieve by an operation should be made. He was accordingly raised in bed to a half-sitting posture, his head turned to the right side, and his left arm moved back out of the way; assistants held him in this position.

I then passed an exploring-needle through the intercostal space between the sixth and seventh ribs, three inches to the left of the sternum, and on withdrawing it water trickled down his side.

A bistoury was then employed to make an incision, two inches in length, through the integuments over the lower margin of the seventh rib.

This was slid upwards by the hand of an assistant to the place where I had previously passed the exploring-needle, and I carefully divided the intercostal muscle when I reached the pleura; this I punctured with a sharp-pointed bistoury, and the fluid discharged with a force that carried it at least ten or twelve inches from his side. It continued to flow until we had a common water-pail half full of a thin slightly albuminous liquid weighing thirteen pounds.

During the discharge of the effusion the heart gradually returned from its abnormal position near the right axilla towards the sternum, and the patient, instead of becoming faint or exhausted, expressed himself greatly relieved. He was gradually reclined over the edge of the bed till he was placed fully on his left side, and at the first sound of ingress of air the integuments were slid downwards, and the wound closed with adhesive plasters and bandage. There was no return of the effusion, and the wound was never reopened. He rapidly improved, and completely regained his health.

The disease left him with the left side of the chest slightly contracted, but the lung was healthy, and he

was able to follow the laborious occupation of a house-carpenter.

Upon motion the Society then adjourned, deferring the discussion upon Dr. Davis's paper until the next meeting.

REVIEWS AND BOOK NOTICES.

A System of Oral Surgery: Being a Consideration of the Diseases of the Mouth, Jaws, and Associate Parts. By James E. Garretson, M.D., D.D.S., Oral Surgeon in the Medical Department of the University of Pennsylvania, late Professor of Principles and Practice of Surgery in Philadelphia Dental College, etc. Illustrated with numerous steel plates and wood cuts. Philadelphia, J. B. Lippincott & Co., 1873.

In the preparation of this voluminous work, in which the author has attempted the difficult task of supplying the needs of the medical man and of the dental practitioner, he has drawn upon an experience not only of wide extent in oral surgery, but also embracing the full range of a general surgical practice, having enjoyed, particularly in the former direction, peculiar advantages for practice in his connection with the University of Pennsylvania. He does not, however, merely present his own experience and opinions, but has drawn largely upon the recorded observations of other authors. Although this may be open to the objection of increasing the size of the book, it adds much to its value, as the reader is thus enabled to compare the various views entertained by eminent histologists and pathologists on the points discussed. The work indeed has been so thoroughly revised, and in many parts rewritten, that it may very properly be esteemed a new book, rather than a second edition of the previous effort of the author. It opens with a concise description of the anatomy and physiology of the oral cavity; followed by the consideration of the pathological aberrations, which, with the therapeutical, surgical, and mechanical treatment indicated in the various affections, are given with a care and attention to detail that will prove of inestimable value to the practitioner, whether engaged in some trying and difficult operation, or in those of a more simple character. The past few years have been remarkably fertile in the production of ingenious labor-saving inventions; all of these have received due attention from the author. Considerable space is devoted to the consideration of Tumors. All tumors are placed under one of two heads,—the "self-explainable" and the "non-explainable;" hernia, dentigerous cysts, steatoma, ranula, hydrocele, aneurisms, etc., belonging to the first class, as such tumors "are in themselves necessarily benign." Every tumor, no matter what its histoid nature or what its situation, that is without a local self-explanation, is placed in the second class, being tumors of a vice expression. While by no means prepared to agree with all the views advanced by the author on this subject and in other directions, we recognize that he has made it one of careful and laborious investigation, and that his opinions are therefore entitled to respectful consideration, particularly as the main object is simplicity in the classification of tumors so as to aid in arriving at an accurate diagnosis. In the perusal of the work and in the preparation of this brief notice of its contents, we have not been indifferent to the unceasing devotion of the author for many years past to his theme, and, sympathizing in the aim to produce a comprehensive treatise on the subject, we have sought out its excellencies rather than endeavored to detect and magnify errors. The work is profusely illustrated, and commends itself alike to the physician, surgeon, and dentist, as a valuable and practical work of reference. The typography and general mechanical appearance sustain the reputation of the house from which it emanates.

BOOKS AND PAMPHLETS RECEIVED.

A Treatise on the Theory and Practice of Obstetrics. By William H. Byford, A.M., M.D., etc. etc. Second Edition; thoroughly revised. 8vo, pp. 469. New York, William Wood & Co., 1873.

The Diseases of the Stomach. Being the Third Edition of the "Diagnosis and Treatment of the Varieties of Dyspepsia." Revised and enlarged. By Wilson Fox, M.D., F.R.C.S., F.R.S., etc. etc. 8vo, pp. 236. London & New York, Macmillan & Co., 1872.

A Treatise on Apoplexy, Cerebral Hemorrhage, Cerebral Embolism, Cerebral Gout, Cerebral Rheumatism, and Epidemic Cerebro-Spinal Meningitis. By John A. Lidell, A.M., M.D., etc. etc. 8vo, pp. 395. New York, William Wood & Co., 1873.

Dental Caries and its Causes. An Investigation into the Influence of Fungi in the Destruction of the Teeth. By Drs. Leber and Rottenstein. Translated by Thomas H. Chandler, D.M.D., etc. With Illustrations. 8vo, pp. 103. Philadelphia, Lindsay & Blakiston, 1873.

Myringectomy, followed by Decided Improvement in the Hearing-Power, etc. By J. S. Prout, M.D., of Brooklyn, N.Y. (From the Transactions of the Medical Society of the State of New York, 1872.) 8vo, pp. 10. Albany, 1873.

Transactions of the Medical Society of the State of West Virginia, for 1872. 8vo, pp. 432. Wheeling, 1872.

GLEANINGS FROM OUR EXCHANGES.

Development of Carcinoma (Waldeyer: *Virchow's Archiv*, 1872, lv.).—This paper contains the results of an examination of 203 cases of primary carcinoma. In 54 cases of carcinoma of the outer portion of the skin, the author makes the following classifications: 1. *C. adenoides*, which closely resembles simple hyperplasia of the glands. 2. *C. papillare*, of which *fibroma papillare* is the prototype, from which it is distinguished by proportionately greater development of epithelium, which fact really decides the character of the tumor. 3. The deeper-seated medullary cancer. 4. The reverse of this form, *C. cutis superficiale*, to which we must join *ulcus rodens*.

In this form of cancer we find at the edges, near the healthy tissue, vascularization of the epithelium. In some cases the capillaries extend into the epidermis, and at the borders of the vessels we find numerous cells which must be considered white blood-corpuscles.

In connection with this excessive growth of epithelium we often find great infiltration of the connective tissue, with new elements, so that between the masses of epithelium true granulation-tissue is found, and we then have *C. granulosum*.

In this form Waldeyer has discovered a transition to certain forms of lupus, in which he likewise found abnormal growths of the rete Malpighii extending into the lupoid granulation-tissue.

5. *C. keratoides.*

In all these forms it is readily shown that the development of the characteristic cell-cones originates from the interpapillary depressions of the rete; sometimes, though rarely, from the hair-follicles and sudoriferous glands. The processes which occur on mucous membranes covered with layers of pavement-epithelium are analogous. Cancers of the uterus, especially those forms belonging to this head, *i.e.*, those of the *portio vaginalis*, show a great inclination to the growth of granulations of the highly vascular stroma, and hence they cause frequent and profuse hemorrhages.

The author next speaks of cancerous forms found in organs possessing cylinder-epithelium, and cites four cases of rectal cancer and two cases of cancer in the large intestines.

The development of the cancerous bodies originates in the follicles of Lieberkühn. In ulcerative forms of cancer of the stomach it is very difficult to decide between carcinoma and simple *ulcus rotundum.*

In fifty-nine cases of carcinoma of the mamma, it was readily seen that in the beginning there is a constant increase in size of the glandular acini, with separation of the same from each other by periacinous growth of small cells. In primary cancer of the kidney and liver it is not difficult to find the origin of the cancerous growths in the uriniferous tubules and the gall-ducts.

Respecting new formations in the brain, Waldeyer is disposed to regard these as plexiform angio-sarcoma, containing cell-elements derived from the perithelial cells of the smallest vessels. He also thinks that there is no proof of the primary occurrence of true cancer in organs *which do not contain epithelium*, as, for example, bone, muscle, lymphatic glands, the heart, blood-vessels, the spleen, serous membranes, and subcutaneous connective tissue, or at least its appearance must be classed among the greatest rarities. In closing his work on the growth of cancer, Waldeyer repeats his theory that all carcinomatous growths originate in pre-existing epithelium, so that the terms cancroid and carcinoma need not be used for purposes of distinction. Cancer is therefore *abnormal* or *atypical epithelial tumor.*

Case of Extra-Uterine Pregnancy (by Dr. Soyre: *Le Mouvement Médical*, January 4, 1873).—The woman was seen in the city by MM. Chantreuil and Guéniot. It was thought, on examination, that she had a fibroid tumor of the uterus, or else that dropsy of the amnios existed. The possibility of the existence of a twin pregnancy was also, for a time at least, thought of.

The patient was sent to the Hôpital des Cliniques. The diagnosis remained uncertain. For the purpose of relieving the dropsy of the amnios a stylet was introduced to perforate the membranes. Perforation of the uterus was the sole result of this operation. The woman died; and it was found at the autopsy—1, that the tumor consisted of the placenta and large clots of blood; 2, that the case was one of extra-uterine (abdominal) pregnancy; 3, that *hydramnios* really existed.

MM. Chantreuil and Guéniot insist on the difficulties of the diagnosis. In this case, the laminated blood-clots surrounding the placenta, attached to the posterior surface of the uterus, imparted to the touch the sensation of a fibrous growth. M. Lionville has recently seen a case of extra-uterine pregnancy at the Hôtel-Dieu, in which the blood-clots were also quite numerous.

A Case of So-Called "Wandering Liver" (Winkler: quoted from the *Centralblatt f. Med. Wiss.*, No. 40, 1872).—Three cases of this abnormal condition have been described by Cantani, Piatelli, and Meissner. To these Winkler adds the fourth case of abnormal mobility of the liver.

In the case related by him, it was possible to press the hand high up into the *excavatio diaphragmatica*, between the costal arch and the liver. In the upright position the liver reached as far as the anterior superior spinous process, and was twisted forward upon its transverse axis. The organ could be replaced. Palpation revealed a normal form and consistence of the liver. The lengthened suspensory ligament could be felt as a sharply defined membranous surface. The cause in this case, as in the other cases, was persistent relaxation of the abdominal wall after pregnancy. An explanation of the icterus in this case may be found in the injury and torsion of the tissues entering the hilus of the liver. The treatment consisted in the application of a firm bandage, made to press from below upwards.

The Thermometer as a Means of Diagnosis in Cases of Uræmia (*Lancet*, Jan. 4).—M. Hanot recently presented to the *Société de Biologie* the notes of a case in which death occurred through uræmia in a patient affected with general paralysis. The uræmic symptoms were produced by pressure of an enlarged carcinomatous uterus on the ureters, and consisted chiefly of a sort of coma and stertorous breathing. The diagnosis was rapidly made out, and the case distinguished from cerebral hemorrhage and softening by means of the rule set down by Dr. Bourneville of considerable fall of temperature in uræmia. In this instance the thermometer showed 34° C at the outset of the symptoms, the following morning 30°, and at the time of death only 20°.

Calabar Bean in Constipation.—M. V. Subbotin recommends, in cases of constipation, the following formula:

℞ Ext. physostigmæ ven., gr. iij;
Glycerinæ, f℥ij.

M. S.—Four drops four times daily.

MISCELLANY.

University of Pennsylvania.—On Saturday last, February 8, by invitation of the Trustees, a large number of influential and representative men, many of them members of the Constitutional Convention or of the State Legislature, met in the new University Building, Thirty-fourth and Locust Streets. A most interesting and instructive tour of the various departments was made, under the guidance of Professors Genth, Lesley, and Frazer, after which a collation was served, followed by several addresses, chiefly from gentlemen connected with the institution. Hon. Morton McMichael presided. Prof. Lesley presented briefly, but clearly, the good work done and doing by the Academic and Scientific Departments. Rev. Dr. Beadle, on the part of the Board of Trustees, made a singularly forcible and telling speech in vindication of the broad, catholic basis upon which the University is now placed. He was followed by Prof. D. Hayes Agnew and Dr. William Pepper, who presented more prominently the present position of the Medical Department, and the urgent need of a further legislative appropriation to insure the completion of the new Hospital Building. The closing remarks were made by Hon. Mr. Chalfant, of the State Senate, assuring the audience of his warm sympathy with this latter project. Our readers may remember that the last Legislature appropriated $100,000 towards the erection of

the University Hospital, dependent upon the subscription of $250,000, which has since been obtained and the appropriation secured. The plans which have been adopted for the building call for an expenditure of over $200,000; and application has now been made for a second legislative grant of $100,000 contingent upon the subscription of an equal additional sum.

We learn that the prospects for securing both this appropriation, and that asked for by the Trustees of the Jefferson College for a similar purpose, are encouraging. It is our earnest hope that they may both succeed, and thus enable the two schools to provide the enlarged clinical facilities for their students which are so much needed in this city at present.

A NEW periodical, the *Medical Record*, has made its appearance in London. We presume the British medical mind will be undisturbed by the fact that the *Medical Record* of New York is in its seventh volume. And yet we do remember the howl that arose when our modest enterprise was begun, under the title *The Medical Times*, because *The Medical Times and Gazette* was already prosperously established. Either our action was innocent, or this "adoption" of the entire title of an existing journal is a very flagrant violation of the proprieties.

AN enterprising publisher in London has begun the issue of a series of photographic portraits of eminent medical men, now living, with biographical sketches, said to be revised by the subjects themselves. But the style of the sketches is so highly laudatory that Sir Thomas Watson has felt called upon to disclaim having either prepared or revised the one relating to him; and a similar denial has been made on behalf of Sir William Fergusson.

PRIZE.—The Venetian Institute of Science, Literature, and Art will, says *Le Mouvement Médical*, award, in 1874, a valuable medal to the best work on the following topic: To show the advantages to medical science, and especially to physiology and pathology, of the modern discoveries in physics and chemistry; with a retrospective summary of the systems of medicine which have prevailed in the past.

NEW JOURNAL.—The same periodical mentions the receipt of numbers of a journal entitled the *Gazette Médicale de Bordeaux*, issued on the 5th and 20th of every month, sixteen pages octavo. The editor-in-chief is M. Fleury.

STILL ANOTHER.—From the same source we learn that a new obstetrical and gynæcological journal has appeared in Paris, entitled the *Gazette de Joulin*. "This title," it is said, "adopted to prevent confusion with any other similar publication, shows sufficiently that the editor is willing to assume the entire responsibility of his work."

MR. CARDEN, of Worcester, England, who died lately, had much to do with the restoration to favor of the operation of amputation at the knee.

M. CYON, who recently received the honors of the French Institute for his discoveries in regard to the nervous system of the heart, has been nominated professor of physiology in the Académie Médico-Chirurgicale at St. Petersburg.

IT is stated by telegraph that the French government, without stating its reasons for doing so, has issued an order directing the closing of the medical school at Montpellier.

THE death of M. Dubois (d'Amiens), perpetual secretary of the Académie de Médecine, is announced.

M. PIERRE CH. HUGUIER, of Paris, died on the 12th of January, aged 68 years.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending February 8, 1873, were 335; 195 adults, and 140 minors. 11 were of bodies brought from the country; making the mortality of the city 324. Among the causes of death were:

Consumption of the Lungs	62
Other Diseases of the Respiratory Organs	57
Diseases of the Circulatory Apparatus	17
Diseases of the Brain and Nervous System	67
Diseases of the Digestive Apparatus	15
Zymotic Diseases (2 from Smallpox)	27
Typhoid Fever	2
Casualties	8
Exposure	1
Murder	1
Suicide	1
Cancer	6
Debility (including "Inanition" and "Marasmus")	24
Still-born	12
Old Age	10

(The interments reported for the week ending February 10, 1872, were 500.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER.		BAROMETER.
	Max.	Min.	(2 P.M.)
Feb. 2	22.0°	14.0°	30.53 in.
" 3	36.0	17.5	30.17 in. (Rain.)
" 4	47.0	36.0	29.85 in.
" 5	40.0	32.0	30.33 in.
" 6	45.0	30.0	30.30 in.
" 7	40.0	36.0	29.84 in. (Rain.)
" 8	44.0	35.0	29.88 in.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 28, 1873, TO FEBRUARY 3, 1873, INCLUSIVE.

DE WITT, CALVIN, ASSISTANT-SURGEON.—To accompany Troop "K," 1st Cavalry, from Reno, Nevada, to Camp Bidwell, California, and, on arrival, report to the Commanding Officer of that post for duty at Camp Bidwell, or in the field. S. O. 12, Department of California, January 20, 1873.

CAMPBELL, A. B., ASSISTANT-SURGEON.—Assigned to temporary duty at Chicago, Illinois, to examine recruits. S. O. 21, War Department, A. G. O., January 25, 1873.

SATURDAY, FEBRUARY 22, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

(Continued from page 307.)

PHLEGMONOUS LARYNGITIS.

LARYNGITIS phlegmonosa (Bouillaud); *laryngitis submucosa* (Cruveilhier); *angina laryngea infiltrata* (Sestier).

This is a form of laryngitis in which the inflammatory processes affect especially the sub-mucous tissues. Though there is no doubt that it occurs sometimes as an idiopathic inflammation, it is seldom encountered as a primary affection, but rather as a secondary one following in the wake of erysipelas, typhus fever, pyæmia, and so on. It is to be distinguished on the one hand from œdema of the larynx, and on the other from the sero-purulent infiltration of the sub-mucous layers occurring in some cases of inflammation of the laryngeal mucous membrane. It is also to be discriminated from true erysipelatous laryngitis, with which it is not unfrequently confounded. For this discrimination we are mainly indebted to the researches of Bouillaud, Cruveilhier, Valleix, and Sestier.

This serious affection terminates in suppuration with destruction of the connective tissue, and sloughing of the superjacent mucous membrane; and in some cases leads to perichondritis and necrosis of the cartilages, principally the arytenoids. Chronic or permanent thickening of the sub-mucous connective tissue ensues, which may result in stenosis of the larynx. The mucous membrane is very apt to participate in the inflammation, sometimes in a great degree, perhaps always to some extent. Occasionally the inflammation spreads to the sub-mucous layers of the pharynx, and to those of the soft palate; under which circumstances it is apt to set up acute inflammation of the cervical and submaxillary lymphatic glands.

Its most frequent seat is the upper portion of the larynx, the base of the epiglottis, and the arytenoepiglottic folds, causing tumefaction of these structures, but to a less extent than that met with in œdema of the larynx.

It has been found beneath the glottis; but here it seldom gives rise to much respiratory trouble. The case of subglottic œdema related by Gibb, in which he found the infiltration simulating a morbid growth, was evidently of this nature.

Rokitansky remarks that the inflammation of the laryngeal sub-mucous connective tissue spreads thence along the inter-muscular and even subcutaneous connective tissue of the neck; and sometimes even starts from here. In these cases there is usually extensive sloughing, with fatal termination.

The symptoms of sub-mucous inflammation of the larynx are similar to those of œdema of the larynx; but they are less in degree, slower and more gradual in their appearance, and are attended with the phenomena of fever. Time is required for the inflammatory process to terminate in suppuration.

The treatment advocated for this affection is the early application of leeches externally, followed by warm fomentations, and free and extensive incisions from the exterior of the throat down to the purulent accumulations; but, as stated by Porter, we must not entertain too favorable an opinion of their efficacy. He says, "If the infiltration was limited in extent, or consisted of a serous fluid alone, or if it could be reached, or, being reached, could be evacuated, there would be a reasonable chance of relief for the patient; but the very opposite of these conditions is generally the true one. In diffuse inflammation of the neck, incisions may be made down into the diseased structure without giving exit to a teaspoonful of fluid, and, after death, the entire cellular tissue of the part engaged may be found of a dark-green and sometimes of a brown color, dead, putrid, and horribly offensive. The difficulty of breathing, however apparently severe, is only a secondary consideration; and even if removed, the patient would perish nevertheless of that low and typhoid condition which always attends these affections."

For similar reasons, Porter cannot admit even the contemplation of the operation of tracheotomy, which, he says, "could not succeed, and would not even possess the miserable second-rate merit of being a last resource, or offering a patient a chance of life." Nor is it recommended by Mr. Gray;* but Dr. Gibb thinks that it should be attempted to hold out a chance for life; and he mentions, in his work on "Diseases of the Throat," a case in which a very difficult tracheotomy was successfully performed, by Dr. Pollock, in St. George's Hospital.

ERYSIPELATOUS LARYNGITIS.

Though there can be no doubt that erysipelatous laryngitis occasionally occurs as an idiopathic affection, most of the cases which have been reported were encountered in hospital practice during the prevalence of epidemic erysipelas; but, since the general institution of the hygienic measures at present in force in every well-conducted hospital, it has been encountered much less frequently than formerly. It is usually attended with an erysipelatous inflammation of the palate, pharynx, or tongue, and sometimes preceded by a manifestation of this nature, which may extend from these structures outwards over the cheek. Sometimes the erysipelatous laryngitis occurs as an extension of external ery-

* Holmes's System of Surgery, vol. iii. p. 232, "Diffuse Inflammation of the Cellular Tissue of the Larynx."

sipelas of the scalp and face. Sometimes it* occurs as a sudden metastasis from erysipelas in some other portion of the body, and subsides externally† on its engaging the internal structures.

It is liable to terminate in œdema of the larynx, and thus to prove fatal by asphyxia. Diffuse abscesses of the sub-mucous connective tissue often ensue from the inflammatory process, the sloughs from which, on examination after death,—for this disease is almost invariably fatal,—present an appearance similar to that of analogous sloughs in the subcutaneous connective tissue, the result of erysipelas occupying the surface of the body. The depots of pus in these instances are found upon the external surface of the larynx, as well as in its interior, and may involve the epiglottis as well as any of the laryngeal cartilages. The trachea is sometimes invaded by the erysipelatous inflammation, and presents similar manifestations in its sub-mucous tissue.

The lecturer stated that his opportunities for observing this disease had been so few in number that he should rely mostly on the records of other observers for statements of the appearances manifested.

Dr. Gibb,‡ in his account of the affection as observed by himself, mentions that the sore throat is preceded by shivering and fever, there being "vivid redness and swelling of the fauces, difficulty of swallowing, and pain in the larynx," adding, that "the voice is hoarse, sometimes whispering, and, what is perhaps an early and an unfavorable sign, urgent dyspnœa is present." He also states that it is fortunate for the patient if the erysipelas appears externally, as there is then a prospect of recovery, for the activity of the symptoms subsides, and they gradually disappear.

In a case where the head and face were primarily affected with erysipelas, which had thence extended to the throat and larynx, Dr. Gibb found, upon making a laryngoscopic examination, "that the fauces were of a bright and shiny scarlet redness, and so was the mucous membrane covering the laryngeal surface of the epiglottis, the interior of the larynx, the vocal cords, and the trachea, associated with tumefaction, but not at that moment affected with œdema."

Ryland has detailed some cases in which there was no connection with external erysipelas, although erysipelas was prevalent at the time in the hospitals in which these cases occurred.

"Black tongue" is a popular term frequently employed to designate an epidemic erysipelatous inflammation of the throat and fauces. Prof. Gross,§ who observed many cases in 1844–45–46, when erysipelas prevailed extensively as an epidemic in this country, and often invaded the air-passages, thus describes the appearances: "The tongue was dry, excessively enlarged, of a dark livid hue, and incapable of protrusion; the uvula, tonsils, and arches of the palate were deeply discolored, rigid, and œdematous; the sub-mucous cellular tissue of the larynx and trachea was extensively infiltrated with serum, or serum and lymph; the lungs were inflamed, the bronchial lymphatic glands were softened, and the thoracic cavities often contained a considerable quantity of serum and pus. If the patient survived any length of time, profuse suppuration and sometimes even extensive sloughing occurred, abscesses formed in the neck and other parts of the body, and ulcers of different shapes and sizes appeared in the throat. The parotid glands sometimes suffered very severely." After giving a very graphic account of the low typhoid character of the symptoms attending erysipelatous laryngitis, he adds, "The danger of this disease is generally imminent, most of the cases terminating fatally within the first four or five days, the immediate cause of death being asphyxia or exhaustion."

After death the parts are found in a sloughy condition, of a red, brownish, or greenish color, a purulent infiltration occupying the tissues of the epiglottis, ary-epiglottic folds, and even the glottis; a coating of lymph is often seen upon the free surface of these structures. The trachea is apt to be more or less reddened, but the œsophagus generally remains quite free from any traces of inflammation.

As already intimated, most of the reported cases have terminated fatally; still, a few are stated to have recovered. The treatment recommended is nutritive, tonic, and stimulant from the very commencement of the affection, with the use of anodynes to allay pain and repress cough; the most suitable tonics being the tincture of the chloride of iron in combination with quinia. Ryland and Gross favor the use of leeches externally in young and robust subjects, and the subsequent application of blisters. The inhalation of steam from hot water is stated by Ryland to form a valuable topical application, often relieving the dry and inflamed condition of the mucous membrane. Dr. Gibb, in his case, in addition to the nutritive, tonic, and stimulant treatment internally, made a local application, every six hours, of a solution of nitrate of silver, four scruples to the ounce of water. Supraglottic œdema, he states, was about commencing when the topical agent was first applied. In twenty-five hours the most marked relief had taken place, and in forty-eight hours the patient was out of danger and the erysipelas was slowly subsiding externally. When symptoms of asphyxia are present, or when the dyspnœa is excessive, tracheotomy is recommended by Ryland, Gross, and Gibb, but it is unhesitatingly condemned by Porter; nor did the lecturer recollect a single case reported in which the patient was saved by this means. "The progress of the disease," says Porter, "cannot be checked by any operation; and, instead of affording even temporary relief, its tendency must be to accelerate the event." When we reflect that Porter extolled tracheotomy in many cases of laryngeal disease where it was condemned by others, we must give due consideration to this decidedly unfavorable opinion of the efficacy of the operation in this affection.

ABSCESS OF THE LARYNX.

Primary abscess of the larynx is a very infrequent disease. Abscess of the larynx can nearly always

* Gibb, The Throat and Windpipe, p. 232. † Porter, p. 95.
‡ Loc. cit.
§ System of Surgery, 1872, vol. ii. p. 385.

be recognized with the laryngoscope. The first case of this seen was reported by Türck,* but was one of secondary abscess resulting from extensive perichondritis. Many other cases have been observed since, the lecturer having frequently detected them. Navratil† mentions a remarkable case of laryngeal abscess involving the right side of the epiglottis, the ary-epiglottic fold, and the arytenoid of the same side. After the spontaneous discharge of an ounce of blood and pus, on the sixteenth day of the disease, Navratil saw by the laryngoscope the ragged edges of the ruptured abscess, and that it had started from the right ventricle.

A very interesting history of primary abscess, occurring in a child four years old, and terminating in fatal stenosis, will be found in *Schmidt's Jahrb.*, Bd. 118, 1863. Another very instructive case is reported in the *Lancet*, 1868, p. 757, by Dr. Marcet and Mr. Hillman. In this case the abscess was opened twice at an interval of three months, and finally a tracheal tube had to be inserted, which was not removed for several months.

Abscess of the larynx, as a rule, however, is a secondary affection, the result most frequently of perichondritis or of chondritis of the laryngeal cartilages; but in some instances it has ensued upon some systemic disease, such as typhus, pyæmia, glanders, etc.

Abscesses of the larynx, unattended with severe pain or dyspnœa, may yet prove rapidly fatal. Stromeyer relates the case of a cavalryman who was on parade at noon and was suddenly suffocated at five in the afternoon. The tongue and larynx of the man were sent to him by Surgeon Döring. He found an abscess the size of an acorn at the base of the epiglottis, and this had led to fatal œdema glottidis. The man had not reported himself as sick, although he had complained at home for a few days about an uncomfortable irritation in his throat.

Abscesses of the larynx sometimes attend typhus fever. Small abscesses form beneath the mucous membrane, and larger ones beneath the perichondrium. They appear, fortunately, in but few cases, and during the second and third weeks,—sometimes not until the period of convalescence. Sometimes they are associated with similar conditions of the nasal passages, palate, and pharynx. The laryngeal complication is usually indicated by cough and dysphagia. Sometimes œdema of the larynx is also added.

A laryngeal abscess is generally seen in the laryngoscopic mirror as a glistening circumscribed swelling, red in color at its base, sometimes red, sometimes yellowish at its apex. The locations in which abscesses have been most frequently observed are upon the lower laryngeal surface of the epiglottis, upon the inner surfaces of the arytenoid cartilages, upon the inner surface of the meso-arytenoidal fold, and surmounting the eminences of Santorini. An abscess of the larynx will in time open spontaneously into the cavity of the larynx. Under certain circumstances, when it can be seen in the laryngoscopic mirror, it can be punctured by a properly-curved knife. As soon as the abscess is opened, the pus is discharged by cough, and then there is usually immediate relief to all the symptoms of pain, tension, and hoarseness.

Occasionally a second abscess will follow closely on the first, and sometimes be succeeded by a third, or even by a fourth, some months later.

It may happen that a case of abscess of the larynx may be recognized under circumstances of inability to open it. If it should be in such a location as to impede the motions of the muscles controlling the patency of the glottis, whether by pressing upon them or by exciting serous infiltration into their tissue, the question of the propriety of performing tracheotomy will have to be considered, especially if there be any manifestation of a tendency to spasm of the glottis.

CLINICAL LECTURE ON CHRONIC MYELITIS.

BY DR. H. C. WOOD, JR.

Delivered at the Philadelphia Hospital.

Reported by Dr. W. H. PARISH, Resident Physician.

(Concluded from p. 309.)

LET us now consider the case of the other man before us. We shall find it to be of an entirely different nature. His history is as follows:

Nelson S., a native of Indiana, æt. 30, gives us the following account of himself up to the time of admission to this hospital. He has never suffered from syphilis, but has led a most dissolute life, being addicted to the most excessive venery, so much so as to indulge his passion nightly, and often, according to his statements, four or five times during a night. In June, 1871, he for the first time experienced uneasy sensations in the lower extremities, with a weakness of the back. Soon there were positive sharp and shooting pains along the spine, with occasional muscular cramps over most of the person. He was now forced to quit work,—his employment being that of a harness-maker. Yet he continued to walk about for several months, and did not leave off his dissolute habits, though daily losing the strength of the muscles, chiefly of the lower limbs. In September it seems that the pains and cramps disappeared, but there remained a decided paresis of most of the muscles, especially of those of the lower half of the person. General sensation was also diminished. In November, 1871, while walking on the street, his legs suddenly entirely failed him, and he had to be carried home. From that time he was confined to his bed, and in a few days was unable to move the lower extremities in the least. During the succeeding winter there was a feeling as if a cord had been drawn tightly around the upper portion of the abdomen. In December he lost the power of emptying his bladder, and subsequently there was inflammation of that viscus, probably from distention. Afterwards incontinence of urine supervened. The bowels from the first were usually constipated. In February there was marked formication in the lower extremities. On admission to the hospital, May 9, 1872, there was almost complete paralysis of both lower limbs. He was altogether unable to walk, and could scarcely raise his heels from the bed when lying in the supine position. The muscles of the lumbar region were also paralyzed, and he could not turn himself in bed. There was numbness in the left upper and in both lower ex-

tremities. An induced electrical current showed the muscles of these members to respond but feebly, and there was decided loss of electro-sensibility, this loss being most apparent in the right lower limb. The prick of a pin produced strong reflex movements in the left, but not so strong in the right lower limb. There were no muscular spasms, no rigidity; the affected muscles lay quiet and flabby. There was no pain in the back. The bowels were constipated, and micturition, though frequent, was accomplished at will. The sexual functions seemed in abeyance. The urine was free from albumen. There were no evidences of cerebral derangement. The sight and hearing remained unimpaired. On the inside of the left foot the points of the æsthesiometer could not be recognized as two when one inch apart, but on the right foot they could. Nowhere in the left leg could the points be recognized when three inches apart. On the inner side of the right leg they were recognized when an inch and a half apart.

The man was ordered phosphorus, gr. $\frac{1}{50}$ *ter die;* the affected muscles were to be faradized, and a continuous current to be passed along the spine.

On June 1 the man was able to move the right lower extremity with much more facility than on admission; motion in the left lower limb was also slightly improved. Electro-contractility was also somewhat increased in both, the muscles of the upper responding much more decidedly than did those of the lower extremities. A sensation at one time felt, as of sand in the hand, had entirely disappeared. The man was able, but with some difficulty, to raise himself in bed, and could turn himself quite readily. The patient continued to improve until the 13th of June, when his temperature rose to 104° F., with pains in the lumbar and the left iliac regions. These symptoms, with a temperature occasionally getting as low as 100° F., continued until the 25th of the same month. At the beginning of this febrile attack the electricity and phosphorus were suspended. Quinine and other febrifuge medicines were given.

July 1.—Since the 25th of June there has been no fever. There seemed to have been no change in the muscles during the past month. Phosphorus and electricity were resumed.

August 1.—During the last two weeks there has been a slow but steady improvement. The arms have become restored to almost a normal condition. The muscles of both lower extremities seemed less flabby, though both the members were frequently bathed in a cold perspiration. Motion in both has improved. The sexual functions seem in abeyance still, though erections occasionally occur. The electrical treatment has consisted in the passage of a continuous current, obtained from fourteen cells of a large Stöhrer's battery, along the spine; the positive pole being above, the negative below. An interrupted secondary current was also applied; this directly to the affected muscles. These two currents were used on alternate but different days. The phosphorus, with occasional intermissions, had been continued. The constipation required remedies for its relief, and anti-dyspeptic treatment was sometimes resorted to.

December 1, 1872.—The man has been steadily improving. He has for several weeks been able to walk about in the ward with crutches, and now does so with two sticks. The muscles seem to be rapidly regaining strength. Constipation is not so troublesome. The urine is normal, and is passed naturally. There has been no variation in the course of treatment, excepting that strychnia was lately substituted for the phosphorus, but the change did not seem to answer, the patient stating that he had not as good control over his muscles as when taking phosphorus.

The symptoms in this case point first to a state of congestion and exhaustion of the cord; then, as these conditions became more marked, the symptoms became more serious, until positive paralysis resulted from, as I believe, myelitis, which did not, however, reach the condition of actual softening, although of that type. This opinion is founded upon the circumstance that the symptoms have been too persistent for congestion alone, and it seems impossible to restore to their normal state spots of fully-formed inflammatory softening. However, whatever the pathological change may have been, the result has been a triumph for modern therapeutics. Not many years ago this man would have been hopelessly bedridden.

But let us look for the cause of his earlier symptoms and of the final paralysis. Undoubtedly they were all due to excessive venery. Nightly, and occasionally repeatedly each night, he was in the habit of indulging his passion; nor did he desist when the earlier phenomena gave him a friendly warning. Of course many similar cases stop short of the severity of this one, and you, as professional men, must not forget a probable cause of many of the spinal troubles of your patients. Not long ago a man came to me, saying that he had suffered a wrench of the back, and was then experiencing uneasy sensations as of tingling and of formication along the lower extremities, with a diminution of muscular power. He felt nervous and weak generally, with a great loss of strength of the back and paresis of the legs. On pushing some questions, he stated that his wife was afflicted with nymphomania, and that, as a therapeutic measure in her behalf, he for two or three weeks had been having sexual intercourse with her from three to five times nightly.

The interesting feature of the case was that, although he had not had sexual intercourse for some months, the symptoms had not ameliorated in the least, and the man was really in a forlorn condition, scarcely able to attend to his work, whilst the exhibition of phosphorus sufficed in two or three weeks to restore him to his normal state.

During the sexual act there is doubtless a decided reflex excitement, with active congestion of the nervous centres, and especially of the cord. There is always in the crisis of the orgasm a local spasm, as of the seminal vesicles, and a semi-convulsive action of the whole muscular system, which sometimes amounts to a true spinal convulsion, and at all times points to an intense excitement of the reflex centres of the cord. Such functional excitement is always accompanied with more or less congestion, and in the old the blood-vessels of the brain have given way before the congestion attendant upon the orgasm, with the result of fatal apoplexy. After intense functional activity of a nervous centre there usually soon follows a state of more or less exhaustion, with a subsequent and gradual return to a normal condition. If, however, before this normal state is arrived at, the cause of the excitement again operates, the same process of excitement, congestion, and exhaustion is again gone through with. When this is repeated again and

again more frequently than the congestion can be relieved and the exhaustion recovered from, both of these conditions become permanent. The point I want to impress upon your minds is that in such cases there is not merely nervous exhaustion or spinal congestion, but *both together*, and that the congestion and the so-called inflammatory condition of the cord which supervene are really not a nutritive action above, but *below* the normal grade; not an inflammation, such as a phlegmon, but a perverted nutrition, in which all the actions bespeak loss of vital force,—a process more akin to softening of the brain than to acute inflammatory cerebritis.

The form of paralysis due to excessive venery is usually that of paraplegia accompanying inflammatory softening of the cord. I have never seen a case of sclerosis thus caused. With the different stages of congestion and exhaustion, or of inflammatory change, there will be more or less marked aberrations of sensation and motion, or, in other words, more or less complete paralysis.

If you have a patient with the earlier of these symptoms, what shall be your treatment? Of course an essential part of it must be the avoidance of the cause; for otherwise the medicinal treatment will be of no avail. The best way to effect this is to send your patient alone on a tour for a few weeks, if he be well enough. At any rate, insist upon his sleeping in another apartment from his wife, if married; as the only method of maintaining the necessary absolute abstinence is to keep out of temptation.

There are some who recommend ergot in such cases, saying that it produces a contraction of the smaller blood-vessels and thus relieves capillary congestion. Most probably it does have this effect; but I have obtained better results from the use of phosphorus than from any other remedy. As already insisted, when the patient applies for relief the congestion has ceased to be an active one, but is passive and attended with exhaustion. Phosphorus is believed to stimulate the circulation of the cord, and to thus relieve the passive congestion. Whether this be true or not, I feel very sure that it influences the nutrition of neural structures to a greater extent than any other known drug, not excepting strychnia. The latter is a powerful functional motor stimulant, but its power of influencing the nutrition of the cord is comparatively slight. Do not give phosphoric acid and think you are giving phosphorus. If you wanted the effects of sulphur, you would not give sulphuric acid. Be careful, too, in administering phosphorus in the pill form. Remember that the least particle of solid phosphorus coming in contact with the stomach will produce an ulcer,—a not insignificant complication. Dr. Percy, of New York, has lately suggested cacao butter as a suitable vehicle. This, he states, when melted, which it does at 100°F., will readily dissolve phosphorus, and thus, when cooled, an oily solution of the drug can be given in the pilular form. I have not put this suggestion to the test, and hence am unprepared to pronounce on its value. I have generally used an oily solution: phosphorus gr. xij in ol. olivæ f℥i. Of this I begin with one minim in mist. acaciæ, and gradually increase it to three or four minims thrice daily. The effect on the stomach must be watched; and if dyspeptic symptoms show themselves you must suspend its use. This drug will be found of considerable value in other cases of perverted nerve-nutrition, such as hypochondriasis and hysteria.

Electricity is another remedy that must not be neglected in the treatment of the various degrees of paralysis following excessive venery. It is, however, doubtful if an electrical current ever reaches the spinal cord. When passed along the spine, it never produces the least muscular movements; and yet if the cord of an animal be exposed and the electrodes be applied directly to that structure, violent muscular spasms will immediately occur.

There seems to be but little doubt, however, that a continuous electrical current passed along the spine is attended with positive benefit; but the good it does is most probably due to a reflex influence on the cord.

I am very much in doubt as to the possibility of galvanizing the sympathetic nerve when unexposed. Our attempts are never attended with any of the symptoms of irritation of that structure. The pupil has never thus been made to dilate; and it is hardly reasonable to suppose that any contraction of the blood-vessels takes place, as in all experiments on the lower animals the pupil has dilated *before* the blood-vessels became contracted.

In addition to the continuous current to be passed along the spine, let the individual muscles be faradized. Know your anatomy, and apply your current to each affected muscle, and thus give each exercise at least every other day, so as to check the tendency towards fatty degeneration which always accompanies the disuse of a muscle. Sometimes you will find the muscles to respond more decidedly to a slowly interrupted or to a continuous current. I have found that this current acts most forcibly upon the muscles when, instead of being simply interrupted, the currents are quickly reversed, by means of a pole-changer, at intervals of from one to a few seconds. In this way I have often been able to get a very active response in cases in which the induced current failed entirely, and the direct or continuous current applied in the ordinary manner produced only very slight results.

There is a simple rule in making a choice of the kind of current. Use a continuous or an induced current, as the one or the other produces the most muscular response. The muscles should also be daily rubbed and thoroughly kneaded, and stimulant embrocations may often be employed with advantage; and as soon as your patient can walk, even with crutches, cause him to exercise himself thus daily, but not to such a degree as to produce fatigue.

[January 27, 1873. The case No. 1 (supposed sclerosis) has, without specific treatment, improved in so far that, the tendency to spasmodic movements in his legs having nearly ceased, he is able to sit in an invalid-chair. There is also some apparent gain of power in his legs; but he is unable

to stand, and it is somewhat doubtful whether the apparent gain of power is not merely owing to the subsidence of the motor disturbance.

Case No. 2 (chronic myelitis), under the use of the treatment previously employed, has gained steadily since the date of the lecture (Dec. 5), with the exception of about two weeks, during which the hypodermic use of strychnia was tried with decidedly bad results. He now walks very well with the aid of a single cane, and can walk alone, although with a hesitating gait, which he says is due to weakness of the ankles. Shutting his eyes increases his embarrassment, but does not stop his walking.]

ORIGINAL COMMUNICATIONS.

THE MICROSCOPICAL STUDY OF BLOOD AND EPITHELIUM.

A Communication to the Biological and Microscopical Section of the Academy of Natural Sciences.

BY JAMES TYSON, M.D.,

Lecturer on Microscopy and Urinary Chemistry in the University of Pennsylvania; one of the Attending Physicians to the Philadelphia Hospital, etc.

IT is scarcely possible to study blood satisfactorily with a power of less than 300 to 500 diameters, such as is obtained with an American or English $\frac{1}{4}$-inch or $\frac{1}{5}$-inch object-glass with the B eye-piece being suitable, and it will often happen that a higher power will be of signal advantage. If a drop of the newt's or frog's blood be placed on a glass slide and gently covered with thin glass around the edges of which a little plain oil is applied with a camel-hair brush, a preparation is made which may be studied for hours.

The nucleated oval red blood disks of these animals will be readily detected; though it must be remembered that the nucleus is not at once visible in the blood just removed from the animal. In a few minutes, however, it makes its appearance, and grows slowly more and more distinct, until it becomes the characteristic feature of the red blood disk, and will always serve to detect it. In many disks, in a simple oil preparation the nucleus remains for a long time invisible.

More difficult of detection, as well as more interesting, is the *white blood corpuscle*.

1. A little careful examination, however, will soon enable the beginner to recognize one form of these corpuscles here more easily than in human blood, because of its distinctly round, or, more accurately speaking, *spherical* form, as distinguished from the oval red blood disk. It also remains isolated, having no tendency to aggregate with others of the same kind, or with the much more numerous red disks. The round corpuscle being discovered, this first form is promptly associated with its decidedly *granular* appearance, caused by the presence of numerous highly refractile particles, whence the name *granular blood corpuscle*.

2. In addition to these, *smaller round cells*, paler and less distinctly granular, are found in the blood of the frog at all periods of the year. They correspond in size and character with the nuclei of the red blood disks. Others again of these are quite as large as the granular cells.

Some of these round cells appear as though perforated in one spot by a "punch," an appearance which might on hasty observation be attributed to the presence of a nucleus, but it is more decidedly circular and sharply defined. These are called "vacuoles," and the white corpuscles containing them "*vacuole cells*."

Careful examination of all these forms will reveal changes of shape, but very much less lively than in the next form of corpuscle—

3. *The Amœboid Cell.*—The blood of the cold-blooded animals affords a most convenient field of study for these cells, since no elevation of temperature is ever required to induce them. The locomotive movements associated with the changes of form should also be patiently looked for. A large number of these cells can be demonstrated by placing a drop of newt's or frog's blood on a thin glass cover, which is placed, drop downwards, over a moist cell, made by applying a ring of putty of suitable diameter to a glass slide and placing a drop of water within its circumference. As the process of coagulation proceeds, and the ring of serum extends itself beyond the periphery of the clot, numerous colorless corpuscles of the amœboid kind migrate from the coagulum into the serum, and may be studied in numbers in this situation.

The property possessed by amœboid cells, during the continuation of their locomotive movements, of incorporating in their structure particles of coloring-matter, milk globules, or even, according to Preyer,* particles of the red corpuscles of extravasated blood of amphibia, should be carefully looked for.

4. A fourth form of colorless corpuscle which should be looked for in these bloods, especially in the spring and summer, is the *fusiform* or *linear-prolonged* cell, first described by Von Recklinghausen in Max Schultze's *Archiv*, Band ii. p. 137. They present a colorless cell-substance with a granular oval nucleus. The term "linear-prolonged" (Klein) is the more applicable, since they seldom, if ever, reach the elongated spindle shape we are apt to associate with the term fusiform, but are rather a "prolonged oval."

Although in these animals the amœboid movement is easily studied at ordinary temperatures, the application of heat greatly accelerates it, and makes it more decided. Increased temperature may be obtained by the careful application of the flame of the spirit-lamp to a metallic plate interposed between the stage-plate and the glass slide, or more satisfactorily by means of Stricker's warm stage. If the temperature, however, be raised above 40° C. (104° F.), the movements cease, and, according to Rollett, the cells harden.

EXAMINATION OF HUMAN BLOOD.

The method of examination of human blood is in no way different from that of the blood of the frog or newt. The circular biconcave shape of the red

* *Pflüger's Archiv*, Jahrgang 1868, p. 423.

disks is well known. The "reversal of lights and shadows" due to this biconcavity, the centre of the blood disk acting as a biconcave lens, and the periphery as a double convex, should be thoroughly studied. Careful focussing will show that the centre is bright and the periphery dark when the object-glass is within the focus, and *vice versâ*, as should be the case on optical principles,—the centre dispersing and the periphery collecting the rays, so that in the former case the more remote negative focus is to be focussed, and in the latter the nearer positive.

The *white* blood corpuscle is not so easy of detection in human blood as in that of animals whose red disks are round. The same general characters, however, belong to it. Its pale, faintly granular appearance, ordinarily round shape, indisposition to unite with others in the formation of rouleaux, and especially its *amœboid* movement, characterize it. The latter, even in human blood, in summer weather or moderately warm apartments, does not require heat to induce it; but it is accelerated by such addition.

Attention should be directed to smaller irregular collections of granular matter, apparently fragments, probably derived by fission or otherwise from the larger white blood corpuscles, and which are undoubtedly what have been mistaken by Salisbury and others for vegetable spores, and especially described by Zimmermann* as "elementary corpuscles," under an erroneous interpretation of their real nature.

In all white corpuscles the granules are subject to the well-known "molecular motion" or "Brunonian" movement, which may be studied with a power of 400 and upwards.

Reagents.—In none of the forms of the white blood corpuscle of the frog or mammalia is the nucleus, as a rule, readily detected without the addition of reagents. Individual corpuscles are found in which this structure is differentiated; but it is by no means general.†

After a little practice with the blow-pipe and gas flame, one can make very delicate and convenient capillary tubes dilated at the middle, so that they approach a spindle shape. These are very convenient for receiving and dropping the various reagents in common use, as the indifferent salt solution, distilled water, dilute acetic acid, etc. They are really much more convenient than any apparatus for dropping yet contrived.

1. *The Salt Solution.*—The first reagent with which blood should be studied is the "salt solution," a half per cent. solution of chloride of sodium, which is also called the "indifferent" solution, since it is intended to act indifferently as a substitute for blood serum, the natural menstruum of the blood corpuscle. *Serum* carefully drawn off from coagulated blood, or *aqueous humor* from the organ of vision, answers the same purpose more satisfactorily, the objection to the constant use of either being only in the difficulty of its preservation. The former may be kept in glass tubes for twenty-four hours, or in cool weather longer; but to avoid inaccurate observation the serum should be nearly fresh. None of these solutions should produce any appreciable effect upon the red or white blood corpuscles; the amœboid movements should continue, and the other appearances remain.

2. The next step is *irrigation with distilled water.* This is done by placing a drop of distilled water at one edge of the extemporaneous blood preparation, and at the opposite edge a narrow strip of bibulous paper, which is replaced by fresh strips as it becomes saturated. Thus is established a current from the drop of distilled water to the opposite edge, and the blood corpuscles are thoroughly "irrigated." The effect of this irrigation—the addition of a menstruum of less density than that in which the corpuscles normally float—is the absorption of such fluid by the corpuscle. This imbibition must be attended by a change of form in the red blood corpuscle, which becomes spherical and smooth instead of biconcave. This change of shape is not always uniform, taking place much more rapidly in some corpuscles, and more rapidly in some directions of the same corpuscle, than in others. The spherical form is assumed because it is that shape which furnishes the greatest capacity. Watching the corpuscle thus distended, the color at first is present. Gradually, however, and sometimes rapidly, as the action of the water continues, the color disappears from the spheroids; they become faint, ill defined, almost invisible, and finally disappear altogether.‡

(To be continued.)

* Rust's Magazine, vol. xlvi. p. 171.

† This is of course not due to any effect of the reagent in producing the nucleus, as has been stated by some, although the latter is altered by the former. That the nucleus is always present in the colorless corpuscle is proven by the use of high powers, in which, in consequence of the large angle of aperture, a more delicate differentiation of light and shadow results, and in consequence the nuclei are always visible even without the use of reagents. This advantage of the high powers was pointed out to me several years ago by Dr. Jos. G. Richardson. For the reason assigned, however, which may not be correct, I am alone responsible. I know of none better. The same is true of the nucleus of the oval red disk, of which we have said above that it is not generally visible by ordinary powers, while the disk is floating in the blood-vessels, or immediately after its removal from the body of the frog or newt. With high powers the nucleus, for the reasons above stated, is promptly discernible.

‡ Here again, for the reason assigned in the previous note, the higher powers enable us to discern the framework of the corpuscle for a longer time after the coloring-matter has altogether disappeared; affording another of the comparatively few instances in this department of microscopic inquiry in which high angle of aperture, rather than penetrating power, of which a low angle is a necessary condition, best serves us.

TRANSLATIONS.

VON OPPOLZER'S LECTURES ON DISEASES OF THE ŒSOPHAGUS.

Being the latter portion of the first part of the second volume of Oppolzer's Vorlesungen über specielle Pathologie und Therapie, Erlangen, 1872.

Condensed from the German of Dr. Emil Ritter von Stoffella,

BY DR. J. SOLIS COHEN.

III.

STENOSIS OF THE ŒSOPHAGUS.

THE *origin of stenosis of the œsophagus* may lie outside of the œsophagus, within the œsophagus, or in its parietes. In addition to this, temporary and recurrent constrictions of the œsophagus occur, due to spasmodic contraction. Extraneous œsophageal stenosis

may be due to various tumors, or to morbid hypertrophies of adjacent structures; such as goitre, tumors in the mediastinum, abscess or tumor in the trachea or between the trachea and the œsophagus, dislocation of the hyoid bone, cancer of the lungs or of the pleura, aneurism of the aorta, scrofulous abscess from caries of the vertebræ, etc. Most authors include enlargements of the cervical lymphatic glands among the causes of extraneous stenosis of the œsophagus; but Von Oppolzer has never seen compression of the œsophagus from this cause.

Intra-œsophageal stenosis may result from impacted foreign bodies; constricting cicatrices, the result of previous inflammation or ulceration, whether traumatic or otherwise; purulent accumulations between the layers of the œsophageal parietes; cancer of the œsophagus; fibroids, polypi, diverticula; morbid growths developed upon other structures and hanging in the œsophagus; thickening of the mucous membrane, and hypertrophy of the sub-mucous connective tissue and of the muscular tissues of the œsophagus; the last cause being more infrequent than the others.

The degree of constriction varies very much. In some instances it is so slight as to be barely recognizable; in others it may amount to almost complete, or even complete, closure. The most frequent seats of stricture are at the cardiac, and at the commencement of the thoracic portion of the œsophagus; but it may exist at any other point. The extent of the stricture is usually small, cases in which the constricted portion measures several inches being very rare. The extent of the constriction is usually dependent on its cause.

That portion of the œsophagus above the seat of stricture is usually dilated, and its parietes are often hypertrophied. If the stenosis has existed a long time, this hypertrophy may have undergone fatty degeneration, under which circumstance that portion of the œsophagus will be nothing more than a flaccid sac. Below the stricture, as soon as the narrowing is considerable, atrophy ensues, as a rule, the œsophagus becoming collapsed, its parietes thinned, and its mucous membrane pale and arranged in longitudinal folds.

The disease always progresses slowly and gradually. At first the impediment to deglutition is noticed only in swallowing hard and large morsels; an effort being requisite to force the bolus downwards. But the first bolus once down, those immediately following rarely produce further difficulty in swallowing. Intermissions of entire freedom from dysphagia, or almost entire freedom, occur at this stage, continuing for days at a time. After a time, small morsels only can be swallowed, and these, often, only after repeated efforts, accompanied sometimes by outside pressure with the hands, or the subsequent swallowing of liquids to force the morsel through the stricture. Finally, solid morsels cannot be swallowed at all, and, in extreme cases, not even liquids. The substance swallowed is returned immediately after deglutition, or a few moments subsequently, and is covered with mucus, alone, or mingled with pus, blood, or cancerous particles, according to the nature of the affection. If a sac-like enlargement of the œsophagus has become developed above the stricture, or paresis of the œsophageal muscles has taken place, then sometimes the ingesta will be detained for several hours, and be regurgitated, in a macerated or semi-decomposed condition.

The *auscultatory phenomena* perceived in stenosis are similar in certain respects to those attending œsophagitis, inasmuch as the swelling of inflammation, or the deposits of exudation, likewise constrict the calibre of the œsophagus.

Hamburger recognizes three grades of stenosis. Stenosis in the first or slightest degree, and which may be so moderate as to evade detection in catheterization of the œsophagus, may be diagnosed on auscultation, by the ascent of a bubble of air or a few isolated bubbles through the liquid bolus. Hamburger's explanation of the physical production of this auscultatory phenomenon is as follows:

"The solid or fluid bolus would be firmly and hermetically grasped by the pharynx and œsophagus during the entire duration of the act of swallowing. The column of air which fills the entire space of the œsophagus below the bolus would be forced through the cardiac orifice into the stomach, whence it would escape, without noise, by the same aperture, on the completion of the act of deglutition. As long as this column of air can escape in the usual way with the same rapidity as the bolus descends, swallowing is comfortable. If, however, at some portion of the œsophagus, its lower third, for example, the calibre is encroached upon by swelling of the mucous membrane, then the column of air below the bolus cannot escape with the necessary and customary rapidity; and the result is on the one side a painful distention of the diseased mucous membrane, and on the other a counterpressure, on the part of the column of air, against the descending bolus. If this bolus is liquid, a portion of the compressed air escapes upwards through the fluid. In these cases we hear, on diligent auscultation, the ascent of one or a few isolated air-bubbles through the liquid bolus after it has glided downwards. Many times this regurgitation of air is not complete,—that is to say, the air is not forced into the mouth; but we hear a sound as though one or more ascending bubbles of air assumed a higher position in the œsophagus, to be fully thrust out at a later moment. Inasmuch as this ascent of air-bubbles is not observed, as a rule, in the healthy œsophagus, it can be taken for granted, with every appearance of verity, in all cases where this slight sound caused by the regurgitation of isolated air-bubbles takes place, that there is a commencing obstruction in the œsophagus at about the locality whence the air-bubbles begin to ascend."*

If the stenosis is further advanced, say to a point corresponding to Hamburger's second degree, then the column of air contained in the œsophagus is so compressed by the descending bolus "that it no longer ascends by one or a few isolated bubbles, but by an entire series of bubbles, which stream rapidly upwards through the liquid bolus to establish their state of equilibrium; and there results the so-called *gurgling*, similar to the sound made on emptying a bottle."† In addition to this, there is an alteration in the form of the bolus, which seems shortened in its diameter. These symptoms of the second degree of stenosis are very variable, according to Hamburger, changing in intensity, or even disappearing, to reappear soon afterwards. It is this variability in the auscultatory phenomena that Hamburger designates as characteristic of this stage,—the increased or diminished amount of constriction in which, he believes to be dependent upon diverse factors; such as the amount of mucus at the seat of stricture, the amount of tension of the muscular coat, etc.

In the more advanced grade of stenosis, Hamburger's third grade, "the compression of the air is still more marked; and, as this compressed air suddenly forces its way upwards, it drives the liquid bolus before it (though not always into the mouth) with a markedly audible resounding noise."‡ Hamburger designates this sound as "resonant regurgitation" (*schallendes Regurgitiren*). As an additional auscultatory evidence of this severe grade of œsophageal stenosis, we hear either no sound at all, during deglutition, along the entire track of the œsophagus below the seat of stricture,

† Op. cit., p. 159.

‡ Op. cit, p. 160.

or at most a slight leakage-sound. If, as is often the case, a dilatation of the œsophagus exists above its constricted portion, certain other auscultatory evidence is obtained, the details of which, to avoid repetition, will be described in connection with the subject of dilatation of the œsophagus.

The *progress* of stenosis of the œsophagus is essentially chronic; modified, in special cases, by the nature of the cause. As a general rule, stenoses of the œsophagus continue for years, if they are not carcinomatous; inasmuch as hypertrophy of the œsophagus above the constricted portion often takes place, in connection with the ordinary dilatation, to such an extent as to be able to overcome the obstruction to deglutition and force the bolus downwards. If the constriction has become very great, or if a paresis of the œsophagus sets in, so that, from one or the other of these causes, fluid nourishment cannot be swallowed at all, or can only be swallowed in insufficient quantity, then a rapidly progressive marasmus ensues, attended towards the last with the abandonment of every effort at deglutition. In some cases the lung undergoes gangrene as a result of inanition; and occasionally, in addition, retro-pharyngeal or retro-œsophageal abscess is developed.

The *diagnosis* is founded principally upon the results of explorations with the œsophageal sound. As additional evidences, we have, besides those furnished by auscultation, the difficulty in swallowing, and the regurgitation of food. By means of the œsophageal sound we endeavor to learn the seat of stricture, its extent, and the amount of encroachment upon the calibre of the passage. Sometimes, by means of a gutta-percha bougie softened in warm water, we can obtain an impression of the form of the stricture. In those cases where the stricture is high up it is also possible to observe it by means of the œsophagoscope.

Having determined that a stenosis of the œsophagus exists, it is necessary to discover its nature. In general this is not a matter of difficulty; but in special cases, where the constriction is due to aneurism of the aorta, or a mediastinal tumor, or a polypus, or a disease of the larynx, etc., it may call for very careful investigation, not infrequently including examination of the larynx with the laryngoscope. If there is no ostensible local cause for the stenosis, such as a burn, or a scald, or the retention of a foreign body, etc., and if examination of the chest, larynx, trachea, vertebræ, etc., reveal no disease which can account for the constriction perceived by the œsophageal sound, then it is quite likely, especially when the patient is rather advanced in life, that the constriction is cancerous. Positive diagnosis of such a condition is confirmed only upon the appearance of broken-up cancerous matter.

An occasional interchange with spasm of the œsophagus might lead to deception early in the case, but not long; for spasm is usually accompanied with other nervous phenomena, continues only for a short time, and then disappears entirely; while in so-called organic stricture the intermissions are only occasionally complete and occur only in the early stages of the affection, becoming less and less frequent as the disease progresses.

The *prognosis* depends upon the degree of stenosis, and the cause which has given rise to it. If the cause is not incurable, and the constriction moderate, a cure, or at least relief, is to be expected from judicious treatment. Unfortunately, this anticipation can only be occasionally realized, by reason of the nature of the causes.

The *treatment* requires, above everything else, a removal of the cause. Foreign bodies must be forced into the stomach, or be extracted; abscesses which press upon the cervical portion of the œsophagus must be opened; polypi which lie upon the inner wall of the œsophagus, or reach into its interior, must be removed by knife or galvano-cautery; and so on.

If there is simple narrowing of the calibre of the œsophagus from thickening of its walls, a result of pre-existing inflammation, absorption of the products of exudation is to be sought for in the internal administration of iodine. Where this cannot be effected, or where the constriction is due to the formation of cicatrices, then we resort to catheterization and cauterization of the œsophagus; methods from which good results have followed in the hands of Gendrin, Trousseau, Bretonneau, and others. Very often the following method, suggested by Jameson and improved by Svicer, will be found the most desirable: a silken string attached to a metallic ball is drawn through a tube; this is then passed down the œsophagus; the tube is withdrawn, and the metal ball, with the string attached, allowed to remain.

In spite of the many methods of dilatation, death may be imminent if relief is not promptly afforded; then there remains only the choice between the operations of internal œsophagotomy and the formation of a gastric fistula. For the first purpose Dolbeau has devised an instrument composed of a thin metallic sound, with an olive-like extremity, in which two small knife-blades are concealed. The end of the instrument is to be carried beyond the stricture, the knives exposed by means of a spring connection, and the instrument withdrawn. In this way the constricted portion of the œsophagus is incised. Dolbeau achieved brilliant results in this way in two cases of very marked constriction of the œsophagus. Trélat, who had previously performed a similar operation, but by cutting from above downwards, acknowledges the greater safety of Dolbeau's method.

Gastrotomy, and the establishment of a gastric fistula, has been recommended by Sédillot and Nasse,* but, so far as Von Oppolzer's knowledge goes, has not yet been performed on the human subject. This course would not be resorted to under circumstances where the cause is itself fatal; for example, in cases of cancer, or in aneurism of the aorta.

If the stenosis is cancerous, everything must be avoided which might compromise the strength and nutrition of the patient. The internal use of iodine or mercury is unjustifiable. The subcutaneous injection of morphia is to be resorted to to subdue pain. The occasional introduction of the œsophageal sound will often be of great service. If catheterism of the œsophagus is no longer practicable, we resort to the use of nutritious enemata and baths, in order to sustain, as long as possible, the waning strength of the patient; though no special success can be hoped for from these measures apart from the advantage of keeping up nourishment.

The employment of electro-therapeutics holds out no hope of success in these cases, speaking from the present stand-point of science on that subject.

Finally, in all cases of stenosis of the œsophagus, let the cause be what it may, nourishment should be administered as far as possible in the form of broths and other liquids, in the most concentrated forms, and in small and frequently-repeated portions. If the stenosis is so great that the patient can no longer swallow any food, we must attempt as long as possible to introduce a tube and inject the nourishment through it.

PRINCE BISMARCK is said to be suffering from chronic poisoning, effected by means of letters sent to him; and his wife, who always aids him in his correspondence, "is suffering from an unaccountable feebleness." As this item comes around by way of St. Louis, and smacks somewhat of a bygone age, we must regard it with some degree of doubt.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 22, 1873.

EDITORIAL.

THE EX-EMPEROR'S CASE.

IT was naturally to be expected that the medical press would comment freely on a case so full of interest, in many points of view, as that of the late Emperor of the French. It is probable that a man in private life, who in 1870 had been able to command the services of such eminent medical advisers, would have been able also to adopt their counsel. For there can be no doubt whatever of the genuineness in every respect of the report drawn up at that time, and signed by M. Sée, but never, for some unexplained reason, either signed by the other consultants or presented formally to the Empress. Those gentlemen, MM. Nélaton, Ricord, Fauvel, and Corvisart, must have known, as did M. Sée, that the Emperor was, from the mere fact of his having a vesical calculus, unfit for the arduous scenes upon which he was about to enter. And, indeed, it must be considered wonderful that the fatal issue was so long postponed, under the excitements and depressions of his subsequent career.

Why lithotrity was preferred to lithotomy by the eminent men who had charge of the Emperor in his last days, does not exactly appear. It seems as if the physical effect of the latter operation would have been more immediately beneficial, while its moral advantage, in the removal of the most palpable offending cause, would have unquestionably been great. Nor can we think that chloroform was without a hurtful depressing influence.

The statement that the cause of death was "failure of the heart's action" means nothing at all. "Uræmic poisoning" would have been the obviously accurate phrase for the lesion.

We cannot understand why there is no mention, in the report of the post-mortem examination, of the condition of the prostate gland. It is merely stated that "the mucous membrane of the bladder and prostatic urethra exhibited signs of subacute inflammation." An exact note of the existence or non-existence of prostatic enlargement should certainly have been placed upon record.

Sir William Gull's additional expression of opinion as to the relation in point of time between the cystitis and the calculous deposit seems to us, if it has any force at all, to be rather a reflection upon the surgical treatment of the case; since the stone certainly existed in 1870, and a cystitis dating so far back would surely have constituted a serious objection to lithotrity.

In conclusion, we cannot but contrast this case with that of the Prince of Wales. In the former, the patient's public position seemed to compel him to neglect his physical welfare; in the latter, it may be said to have been the source of his safety. In the former, the precautions which any laborer could have observed had to be thrown entirely aside; in the latter, there was an unlimited command of every resource of care and skill.

PHYSICIANS AND DRUGGISTS.

IN November last, as we learn from the *American Journal of Pharmacy*, a communication was addressed to the Maryland College of Pharmacy by a committee of the Medical and Surgical Society of Baltimore, enclosing the following preamble and resolution, which had been adopted by the latter body:

Whereas, We, the physicians of the city of Baltimore, have been grossly injured by the practice of druggists prescribing across the counter, and the indiscriminate renewal of prescriptions without the physician's order; and, whereas, we do not consider the course of study usually pursued by druggists as qualifying them for the practice of medicine; and, whereas, we consider such a course as extremely hazardous to the public and very unjust to the physician; and, whereas, we deem it proper that harmony should exist between the physician and druggist, in order to further the interests of both parties, and at the same time to conduce to the welfare and safety of the patient: therefore be it

Resolved, By the Medical and Surgical Society of Baltimore, that a committee of ten be appointed by this Society to lay our grievances before the Maryland

College of Pharmacy, and request the appointment of a similar committee by that body, to devise means to do away with the acts complained of.

The College of Pharmacy acceded to this request, and the desired conference was held on the 14th of January. The rather meagre account of it given in the *Journal of Pharmacy* says that the charges against the druggists were these:

1. Apothecaries prescribing across the counter.
2. Repeating prescriptions without the order of the prescribing physician.
3. Advertising patent medicines by show-cards, bills, etc.

It is further said that

Prof. J. Faris Moore was the principal speaker for the pharmacists, and met the different charges ably and forcibly. In his argument he stated that the physicians were responsible for many of the existing irregularities, that he had a list of not less than seventeen nostrums, including trade deceptions, which were prescribed by leading physicians of Baltimore, from Winslow's Soothing Syrup to Hubbell's Elixir of Valerianate of Ammonia; and that the prescription business could not, therefore, be conducted without keeping quack nostrums. His remarks on the subject of popular elixirs, like a two-edged sword, cut on both sides.

After a long and friendly discussion, the following resolutions were adopted:

1st. *Resolved*, That, although it is perfectly admissible for druggists to sell any article for which customers may ask, whether orally or by prescription, yet it is highly objectionable for druggists to prescribe for customers under any circumstances, except to meet an emergency.

2d. *Resolved*, That, with the permission of the Societies we represent, this Committee of Conference shall solicit the passage of a law by our State Legislature looking to the regulation of the sale of poisons in this State.

3d. *Resolved*, That the display by druggists of signs calling attention to the sale of patent medicines be considered disreputable.

Another conference was to be held on the first Tuesday in the present month; but we have not as yet seen any report of its results. We have before taken occasion to speak of the matter under discussion, and wish that in our own and other cities even stronger action might be taken towards the establishment of a fair understanding between the medical practitioner and the apothecary. It is certain that there is a vast deal of prescribing, and of recommendation of patent medicines, and of redispensing of old prescriptions, on the part of druggists, to the injury of both physicians and the public. More energetic action, and more decided results, than those of the Baltimore conference, are, however, necessary, if any permanent good is to be accomplished.

We cannot but believe that the appointment of the Examining Boards in this and other States, to insure a better class of pharmacists, is a great step in the right direction, and will make it far easier for the medical profession to bring about a truer relation between themselves and those who should be their aids, but who are now too often their opponents.

CORRESPONDENCE.

COLLECTION OF PHYSICIANS' BILLS.

EDITOR PHILADELPHIA MEDICAL TIMES:

SIR,—It is true that a long-followed custom becomes at last almost, if not entirely, a law; no matter how absurd or inconsistent the custom may happen to be. The old established rule among physicians, of rendering their bills for professional services but semi-annually or annually, has been so long followed as to appear as much a law as though it occupied a place on the statute-book. Notwithstanding that such a custom has been long observed and followed up, it has been the means of great injustice being done to the profession generally, and particularly to those just commencing practice, unless they may be possessed of enough of this world's goods to be able to live without reaping any pecuniary benefit from their professional labors. If they happen to be (as is often the case) in circumstances such as oblige them to depend upon their daily earnings for support, and feel in duty bound to follow the custom marked out for them in regard to the periodical rendering of bills, they soon find but a very narrow margin between them and starvation. There are those whose circumstances will allow their accounts to run for an indefinite length of time, knowing that their bills when rendered will be promptly met by a check drawn upon the well-filled exchequers of their worthy patrons; but they comprise but a small minority of the whole profession. Merchants, mechanics, or other business men have no compunctions of conscience in rendering their monthly statements to physicians, and pressing their payment, when they would no doubt feel indignant were their family physicians to send them their bills monthly, instead of semi-annually or annually, as *they* know the custom to be. Mechanics or laboring-men who receive their wages weekly (as is customary) are as well able to settle their accounts on Saturday night as on December 31, and would in all probability settle a small bill with more ease and grace at the end of the week than a large one at the end of the year. The game has become such a losing one to physicians that some change seems necessary, and we only need a move in the right direction,—a move which will require the more frequent rendition of bills, which will in many instances bring about settlements that would have passed

out of mind if six or twelve months were allowed to elapse between the date of attendance and the rendition of a bill for the same. An initiatory step has been taken in this direction by a number of physicians composing one of the coteries in the northwest part of the city, by passing a resolution that in future all bills sent shall have printed on them the words "*Bills rendered monthly*," and that all bills be thus often rendered unless still in attendance on the patient. There seems to be a determination, on the part of the physicians referred to, to follow out the letter and spirit of the resolution, and we hope other organizations, and the profession generally, may give it a trial, and see if much good may not result therefrom. B.

[We may remark that the above views are in entire accord with an editorial headed "Black Lists," in our issue of December 21, 1872. We believe that every physician would gain by simply adopting the plan of sending monthly bills, without waiting for the formal sanction of his fellows for so doing; and that both he and his employers would fare better in the end.—Ed.]

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

SIXTY-SEVENTH ANNUAL MEETING.

Reported by James S. Bailey, M.D.

FIRST DAY'S PROCEEDINGS.

THE Medical Society of the State of New York met at Albany, February 4, 1873, in the public hall, Perry Building. The meeting was called to order by the President, Dr. C. R. Agnew, of New York. Prayer by the Rev. Dr. Clark, after which the President read his inaugural address.

The President then announced the following committees:

On Credentials, Drs. W. H. Craig, A. L. Saunders, and C. E. Rider.

Business Committee, Drs. Ellsworth Eliot, J. V. Kendall, G. H. Hubbard.

Committee on Arrangements and Receptions, Drs. J. V. P. Quackenbush, W. H. Bailey, Darwin Colvin.

Committee on Medical Ethics, Drs. Thomas Hun, of Albany; E. R. Squibb, of Brooklyn; D. B. St. John Roosa, of New York.

The President then introduced Dr. G. W. Barr, of Titusville, delegate from the Pennsylvania Medical Society.

Dr. Eliot, Chairman of the Business Committee, announced a paper by Dr. George Burr, of Binghamton, to be read by Dr. William C. Wey, of Elmira, Dr. Burr being absent. Subject of paper: "A Case of Occlusion of the Femoral Artery from Fracture of the Femur, followed by Mortification and Amputation." It was referred to the Committee on Publication. The Business Committee also announced a paper by Dr. E. H. Bridges, of Ogdensburg. Subject: "Disease of the Left Ovary resulting in Fatal Hemorrhage." Referred to the Publishing Committee.

The following papers were read by title: "Obituary Notice of Dr. Darius Clark," by Dr. B. F. Sherman; "Hernia," by Dr. J. H. Pooley, of Yonkers; "The Effects of Railroad Travel on the Health of Women," by Dr. Ely Van De Warker; "Idiopathic Peritonitis," by Dr. Joseph Lewi, of Albany; all of which were referred to the Committee on Publication.

Dr. D. B. St. John Roosa, of New York, read a paper entitled "History of the Progress of Otology," which was discussed by Dr. Knapp, of New York. It was referred to the Publishing Committee.

Dr. William B. Alley, of Nunda, read a paper on "The Ultimate Result of Nerve-Injuries in Gunshot Wounds," which was discussed by the members of the Society.

Dr. Roosa offered the following:

Resolved, That the Business Committee be requested to consider papers that may be presented by invited members of the Society, and cause them to be read if thought expedient.

The Society then adjourned until 3 P.M.

AFTERNOON SESSION.

Dr. Agnew, President, in the chair.

Dr. J. W. S. Gouley, of New York, read a paper on "Perineal Lithotomy," which was discussed by Dr. Krackowizer, of New York, and Dr. Hutchison, of Brooklyn.

The President announced the following Committee on Nominations:

First District, Dr. J. C. Hutchison; *Second*, Dr. J. Foster Jenkins; *Third*, Dr. H. B. Whiton; *Fourth*, Dr. Alexander Ayres; *Fifth*, Dr. Alonzo Churchill; *Sixth*, Dr. William C. Wey; *Seventh*, Dr. Caleb Green; *Eighth*, Dr. H. W. Dean.

Dr. Vander Poel read his report in regard to changing the time of meeting of this Society.

On motion of Dr. Eliot, the report was received, and the discussion postponed till the evening session.

Dr. Thomas Addis Emmet read a paper on "Laceration of the Perineum, involving the Sphincter, and Operation for Securing Union of the Muscle." It was referred to the Committee on Publication.

Dr. E. H. Parker remarked upon a case of "Dislocation of the Tarsus from the Astragalus," exhibiting the specimen.

Dr. E. M. Moore, of Rochester, read a paper on "Intra-Capsular Fracture," illustrated by two cases. It was discussed by Drs. Gurdon Buck, Douglas, and A. N. Bell.

Dr. Eliot, from the Business Committee, read the following papers by title, and they were referred to the Publishing Committee:

"Case of Fatty Tumors of the Abdomen," by James S. Bailey, M.D.

"Senile Hypertrophy of the Prostate Gland," by James S. Bailey, M.D.

"Unusual Case of Inflammation of the Urinary Organs," by S. T. Clark, M.D.

On motion, the Society adjourned, to meet at eight in the evening.

EVENING SESSION.

The Society came together at 8 P.M., Dr. B. F. Sherman, Vice-President, in the chair.

Dr. E. R. Squibb, of Brooklyn, Chairman of Committee on Pharmacopœia, read his report. The report, on motion, was accepted.

A paper entitled "Dropsy after Scarlatina," by Dr. George Douglas, was read by title and referred to the Publication Committee.

The report of the committee on changing the time of meeting of the Medical Society of the State of New York was then taken up, in accordance with the recommendation of the Business Committee. Various motions and amendments were submitted, and while the matter was under discussion a motion to adjourn to meet at nine o'clock on Wednesday morning was made, seconded, and unanimously adopted.

MORNING SESSION.

The Society met, agreeably to adjournment, at nine o'clock, Dr. AGNEW, the President, in the chair. No clergyman being present, the President opened the meeting with prayer. The Secretary read the minutes of Tuesday's sessions. On motion, they were adopted.

Dr. OLIVER WHITE, of New York, chairman of the Committee on By-Laws, through the Secretary, made his report. The report was received.

Dr. F. N. OTIS, of New York, read a paper on "Strictures of the Male Urethra, with Results of Operation with the Dilating Urethrotome."

Dr. Gouley, of New York, and Dr. Newman, of New York, discussed the paper.

Dr. ROOSA arose to a question of privilege, making remarks and explanations regarding a paper in the Transactions of last year by Dr. Stephen Rogers, of New York.

Dr. JAMES R. LEAMING, of New York, read a paper on "Plastic Exudation within the Pleura." Referred to the Publishing Committee.

Dr. CHARLES H. PORTER, Treasurer, made his annual report. On motion, it was referred to the following auditing committee, appointed by the chair: Drs. J. V. Cobb, H. Corliss, and Staats.

Dr. ELIOT offered the following:

Resolved, That candidates elected to permanent membership who neglect to pay the fee required by our by-law, for one year from the date of their election, shall forfeit their rights as permanent members.

Adopted.

Dr. A. N. BELL read his report on the "Quarantine Establishment of New York," being a report of the Committee on Hygiene.

Dr. A. B. BURGER, of Saratoga county, presented a specimen of a diseased kidney, with a description of the case. It was referred to the Publishing Committee.

Dr. WILLIAM T. LUSK, of New York, read a paper on the "Pathology of Labor Pains." It was referred to the Publishing Committee.

Dr. GURDON BUCK presented a case of reconstruction of the under lip. Referred.

Dr. COBB, of the committee to whom was referred the Treasurer's report, reported that they had examined the same and found it to be correct.

Dr. LEWIS A. SAYRE read a paper on "Diastasis of Head of Femur, and Formation of Artificial Hip-Joint." Referred to the Publishing Committee.

Dr. J. V. P. QUACKENBUSH read a paper on "Hydrorrhœa."

Dr. E. R. SQUIBB reported from the Committee on Ethics regarding the Niagara County Medical Society. The report was unanimously adopted.

An obituary of Dr. P. Van Olinda, by Dr. A. Van Derveer, was read by title and referred to the Publishing Committee.

On motion, the Society adjourned, to meet at 2.30 P.M.

AFTERNOON SESSION.

The meeting was called to order by the President, Dr. AGNEW. Dr. DOUGLAS made his report as delegate to the Connecticut State Medical Society. Dr. CORLISS reported as delegate to the Maine Medical Association. Dr. NEWMAN reported as delegate to the New Jersey State Medical Society.

Dr. JACOBI, from the Committee on Foundling-Asylums, made his report. Dr. JOEL FOSTER made a minority report on the same. On motion, the majority report was accepted and adopted.

Resolutions in regard to the Committee on Nominations, to the act relative to the medical laws of the State, and to the time of meeting of the Society, were presented and laid on the table.

Dr. B. L. HOVEY read a report of five consecutive cases of Colles' fracture. It was referred to the Publication Committee.

Dr. J. P. GRAY exhibited to the Society micro-photographs of brain-tissue.

Dr. H. KNAPP read a paper on "Hemiopic and Sector-like Defects of the Field of Vision, and their Connection with Diseases of the Heart and Brain." It was referred to the Publishing Committee.

Dr. J. P. PALMER, of Victor, Ontario county, read a paper on "Spotted Fever."

Dr. CORLISS read the "Biography of Dr. B. P. Staats, of Albany."

The following papers were read by title and referred to the Publishing Committee:

"Three Cases of Abscess and Pelvic Peritonitis from Ulceration of the Appendix Vermiformis, relieved by Operation," by Dr. R. B. Bontecou, of Troy; "Complete Dislocation of the Tenth Dorsal Vertebra Forwards," by Dr. Graves, of Steuben county; "On the Use of Atropine in Some Diseases of the Eye," by Dr. Edwin Hutchinson, of Utica—sent as a communication by the Oneida County Medical Society.

Dr. BABCOCK reported for the Censors of the Eastern District that they had examined E. V. Stryker and found him well qualified, and recommended him as a proper person to receive a diploma from this Society.

The Society convened in the Assembly chamber at eight o'clock, to listen to the annual address by the President, Dr. C. R. AGNEW.

THIRD DAY'S PROCEEDINGS—MORNING SESSION.

The Society met at 9.30 A.M., the President, Dr. AGNEW, in the chair.

Prayer was offered by the Rev. Mr. REEVES. The minutes were read and approved.

Dr. VANDER POEL, chairman of the Committee on the President's address, read their report, and after discussion it was accepted and adopted.

Dr. ROBERTSON, of Albany, read a paper entitled "Cases in Practice." Referred to the Committee on Publication.

Dr. J. MARION SIMS read a paper entitled "A Case of Enucleation and Removal of an Intra-Uterine Fibroid Tumor," with instrument for the same. Referred to the Committee on Publication.

Dr. WILLIAM C. WEY read a paper entitled "Some Observations concerning the Hypodermic Injection of Ergot in Uterine Fibroids."

It was discussed by Drs. Sims and Squibb, and by other gentlemen, and then referred to the Committee on Publication.

Dr. J. N. NORTHROP, of Albany, presented a case of congenital loss of the right arm, with remarks upon it.

Dr. Jacobi believed that it was a case of arrested development, the reasons for which he explained in full.

The Business Committee read the following papers by title:

"Penetrating Gun-shot Wounds of Cranium, with Recovery," by A. Van Derveer, M.D.

"Sequelæ of a Case of Purpura Hemorrhagica," by H. S. Crandall, M.D.

Dr. C. DEVOL presented two pathological specimens.

Dr. A. N. BELL offered the following:

Resolved, That the Standing Committee on Hygiene be added to, and hereafter recognized as one of, the Standing Committees under section 111, page 20, of Organization and By-Laws of the Society, and that said committee place itself in immediate correspondence with the county Societies.

Unanimously adopted.

Dr. A. N. BELL offered the following:

Resolved, That the Standing Committee on Hygiene

consist of seven members, one of whom shall be Dr. C. R. Agnew; the balance of the committee to be appointed by the chair.

Adopted.

The President appointed the following the Committee on Hygiene:

Drs. A. N. Bell, S. O. Vander Poel, H. D. Didama, H. W. Dean, John Ordronaux, Stephen Smith, C. R. Agnew.

The Nominating Committee reported through their Secretary, Dr. J. Foster Jenkins, the following nominations to office for the ensuing year:

For President, Dr. E. M. Moore, of Rochester; *Vice-President*, Dr. Francis Burdick, of Johnstown; *Secretary*, Dr. William H. Bailey, of Albany; *Treasurer*, Dr. Charles H. Porter, of Albany.

For Censors: Southern District—Dr. E. R. Squibb, of Brooklyn; Dr. E. H. Parker, of Poughkeepsie; Ellsworth Eliot, of New York.

Eastern District—Dr. John P. Sharer, of Herkimer; Dr. James L. Babcock, of Albany; Dr. G. H. Hubbard, of Lansingburg.

Middle District—Dr. M. M. Bagg, of Utica; Dr. Horace Lathrop, of Cooperstown; Dr. C. G. Bacon, of Fulton.

Western District—Dr. Caleb Green, of Horner; Dr. C. C. Wyckoff, of Buffalo; Dr. D. Colvin, of Clyde.

Dr. JENKINS offered a resolution, as a part of the report of the committee, that no one should be eligible for election to permanent membership until he had been a delegate for three years.

Dr. SQUIBB moved to amend this so as to require delegates to be present at the meetings and serve for three years. After considerable discussion, the resolution was carried as amended, and the report of the committee adopted.

Dr. F. B. A. LEWIS offered the following:

Resolved, That this Society extend their sincere thanks to the officers and members of the Albany County Medical Society for their munificent entertainment and warm reception of last evening.

Carried.

Dr. AGNEW made a few appropriate remarks in conclusion of his service as President.

On motion of Dr. ELIOT, the Society adjourned.

GLEANINGS FROM OUR EXCHANGES.

ELEVATION OF TEMPERATURE AFTER THORACENTESIS (Bourneville: *Le Mouvement Médical*, Dec. 28, 1872).—In the April number of the *Revue Photographique des Hôpitaux* (1872, p. 112) we reported the following two cases relating to the effects of thoracentesis upon the temperature:

Case 1.—L. P., æt. 32. Left pleurisy. Before the operation: Pulse, 84; Respirations, 18; Temp., Réaumur, 38°.4.

1200 grammes (about 3½ pints) of pale-yellow fluid drawn off. After the operation: P., 88; R., 24; T.R., 38°.4.

Case 2.—D., æt. 18. Right pleurisy. Before thoracentesis: P., 104; R., 24; T.R., 38°.9.

Three quarts of clear fluid drawn off. After operation: P., 104; R., 24; T.R., 39°.4.

Comparing these results with those that we observed after two abdominal tappings, we stated, "Though the evacuation of fluid contained within the abdominal cavity did not affect the temperature in a very sensible manner, we observe an elevation of temperature following thoracentesis."

The thermic phenomenon observed by us has lately been confirmed by M. Laboulbène, whose researches, contained in the *Gazette des Hôpitaux*, Dec. 21, we will now quote:

Case 1.—Male. Fluid drawn off clear, pale yellow, and fibrinous; 2605 grammes.

T.R. before thoracentesis, 38°.4; after thoracentesis, 38°.6.

Case 2.—Male. Fluid deep yellow, slightly turbid, fibrinous; 2000 grammes.

T.R. before thoracentesis, 38°.6; after thoracentesis, 38°.9.

Case 3.—Male. Fluid slightly turbid, yellowish, but having a rose tint, slightly bloody; 1050 grammes.

Case 4.—Male. Fluid clear, pale yellow, and fibrinous; 800 grammes.

T.R. before thoracentesis, 38°.4; after thoracentesis, 38°.6.

Case 5.—Male. Fluid perfectly clear, of amber color; 1830 grammes.

T.R. before thoracentesis, 38°.6; after thoracentesis, 38°.8.

Case 6.—Male. Fluid clear, slightly greenish, fibrinous; 1360 grammes.

T.R. before thoracentesis, 38°.6; after thoracentesis, 38°.8.

In the eight preceding cases it is seen that the temperature rises from two to five tenths of a degree after the performance of thoracentesis. It is very probable, as M. Laboulbène observes, that this elevation is due to the more regular and more complete performance of the act of respiration, the lung on the side corresponding to the pleuritic effusion being no longer compressed.

The number of cases is still too small to enable us to say whether this thermic phenomenon is a constant one. Attention being awakened to the point, it will undoubtedly not be long before we understand its significance. It will be equally interesting to see what influence is exerted on the temperature by abdominal tappings, by thoracentesis for hydrothorax, etc.

In regard to hydrothorax we ought here to report a very recent case. It is that of a woman, æt. 55, a subject of albuminuria, who occupies bed No. 20 of ward Saint-Alexandre (service of M. Charcot).

Considerable œdema of the lower extremities, ascites, and hydrothorax occurred. On the 26th of December, before the performance of thoracentesis, we noted—P., 96; R., 24–28; T.R., 37°.3. 280 grammes of clear, pale-yellow fluid were drawn off. Immediately after thoracentesis, we found—P., 88; R., 24–28; T.R., 37°.3; and an hour and a half later, P., 90; R., 24; T.R., 37°.2.

The thermometer remained in place the same length of time (four minutes) on both occasions. Ought we to attribute the absence of the elevation of temperature in this case to the relatively small quantity of liquid drawn off, or to the nature of the disease? We do not know; for to be authorized in forming an opinion on this point, it is indispensable to have a large number of cases.

A NEW ANÆSTHETIC OBTAINED FROM CHLORIDE OF CARBON (MM. Hardy and Dumontpalier: *Am. Journ. of Pharm.*, Feb. 1, 1873; from *Journ. de Pharm. et de Chimie*, Dec. 1872).—Chloride of carbon unites in definite proportions with alcohol, and furnishes a liquid which boils at a fixed temperature and possesses strong anæsthetic properties. To obtain it, 30.8 parts of chloride of carbon are mixed with 4.6 parts of alcohol, the mixture distilled, and the portion collected which boils at 66° C.

It is a colorless, transparent, mobile liquid, of an agreeable odor, and a density of 1.44 at 13° C. and at a pressure of 0.755. Its boiling point, 66° C., is below that of both its constituents, chloride of carbon boiling at 77° and alcohol at 78.5°. It is unalterable in the air,

volatilizes slowly, and burns with difficulty, the flame having a green margin. It is decomposed by water, sulphuric and hydrochloric acids, chloride of carbon being deposited. Aided by a moderate heat, nitric acid attacks it briskly, with the disengagement of red fumes and the separation of chloride of carbon, while the supernatant liquid yields oxalic acid.

Analysis leads to the formula $2CCl_4,C_2H_6O$. Its density, however, which in two experiments was found to be 4.2 and 4.1, does not correspond with the theoretical density required by this formula. Whether it be regarded as a compound or as a mixture, it is curious that it has a fixed boiling point, and all the physical appearances of a body of definite composition. Other analogous cases are known which have not yet been interpreted.

It acts as an anæsthetic, for which purpose its ethereal odor and its low boiling point render its application easy. Experiments were made with a dog of medium size; the mouth was kept closed, the inhalation took place from a sponge through the nostrils so that a certain quantity of air was likewise allowed to enter; fifteen grammes, in three portions, were sufficient. Comparative experiments, made upon the same dog, at intervals of several days, with chloride of carbon and with chloroform, in uniform doses of fifteen grammes, led the authors to the conclusion that the last two liquids act with greater intensity than the new substance, which, however, should be used with the greatest care in experimenting upon human subjects.

Fracture of the Sternum (A. Desprès).—*Le Mouvement Médical* of the 31st of August, 1872, gives the report of the following case, taken from the *Gazette des Hôpitaux*. On the 25th of May, towards midnight, C., 59 years old, a cook by occupation, was attacked, when about to enter his house, by several individuals, thrown down, and beaten. He lost consciousness and remained prostrate for about half an hour; he then succeeded in entering his house, and was obliged to remain in bed for two days following the accident.

Soon after the injury he experienced severe pain in the sternal region and great difficulty in breathing. The pain was increased by motion and by the effort of coughing. When he entered the hospital, under the care of M. Desprès, the following note was made: dyspnœa marked; pressure upon the thorax causes pain; the same is true of motion. The patient coughs with great difficulty. Examination of the chest reveals well-marked ecchymosis in the sternal region, but there is neither deformity nor abnormal mobility; it is impossible to detect any crepitation when the patient is made to cough; his general condition is good; there is nothing particular revealed by auscultation.

On the following day, M. Desprès had a pillow doubled up under the back of the patient, in order to throw the head back and arch the trunk; then, on making pressure over the sternum, crepitation was felt at the middle part of the second piece, and nearly in the centre of the ecchymosis; a certain amount of mobility was also observed.

The case, therefore, was one of transverse fracture of the sternum without displacement.

A diachylon band was applied, and in six days the patient left the hospital, free from pain, excepting on full inspiration.

According to the authorities on the subject, transverse fracture of the sternum is rare; but is it not probable that a certain number, in consequence of incomplete examination, escape observation? This certainly would have happened in the case just related, if M. Desprès had not had recourse to the doubled pillow placed transversely under the back.

MISCELLANY.

The Pharmaceutical Examining Board of Philadelphia have presented their first annual report to the Mayor. They state that they held, from May 20, 1872, to January 1, 1873, fifty meetings for the transaction of business. There were "504 applications for registration as proprietors received, of which number 292 were approved and certificates ordered to be issued. There have been 287 applications from clerks, of whom 250 appeared for examination as to competency and qualification. Certificates as 'Qualified Assistant' were granted to 185 of the applicants, and 65 were rejected as incompetent to be left in charge of a store. Since the passage of the act, 10 persons not graduates in pharmacy who wished to open retail drug-stores have been examined by the Board, five of whom received the necessary certificate of competency, and five were rejected as not possessing the requisite knowledge and qualifications.

"This record shows that of the number applying for the responsible position of proprietor of a store where the most deadly poisons were to be dispensed, fifty per cent. were judged by the Board to be unfit for it, and that only seventy-four per cent. of those who were to be left in charge during the absence of the proprietor were deemed competent for the post. At this date twenty-five proprietors and thirty qualified assistants have not called for or obtained their certificates, although duly notified to do so."

The Board further state that "the receipts from fees have been barely sufficient to meet the expenses, and the Board regrets the inadequacy of the law to provide the means for prosecuting those who violate it. No cases of fraudulent adulteration of medicines have been reported, but the sale of medicines has been continued in some localities by grocers; and copies of the law have been sent to all the retail grocers whose names appear in the business directory, to call their attention to the provisions restricting the sale of poisons and medicinal preparations to registered pharmacists."

Xylol.—We take the following doubtful item from a daily paper:—

"The St. Louis *Democrat* contains the following letter:

"'Baltimore, Md., Jan. 25, 1873.

"'The Superintendent of Police, St. Louis, Mo.:

"'Sir,—I would most respectfully call your attention to the new medical compound known as 'xylol,' which is now being used in this city for purposes of robbing and murder.

"'The mode of application is by mixing it with the feathers in a pillow, and, when the warmth of the head is applied to it, it gives off vapors similar in effect to the fumes of charcoal, and the person using it is found dead in the morning, which gives the monsters who apply the drug ample opportunity to possess themselves of the property of their victims and otherwise dispose of their remains.

"'The drug was tried upon myself here some time

ago by a German Jew, who invited me to stop in his house. I escaped his foul designs, and obtained a knowledge of his intentions and manner of proceeding, by trifling circumstances, the details of which I will not weary you with.

"'But, as I had lately read accounts of several persons being missing in this and other cities, I felt in duty bound to investigate the matter for the benefit of society at large. Consequently, I have devoted my leisure hours to it for the last two years, and have now acquired a perfect knowledge of the drug used, and I lose no time in communicating its name to you, that you may cause the officers under your control to put themselves into communication with the druggists, and keep a system of surveillance over those who purchase it. Hoping that you will also cause a notice of the hidden qualities of the drug to be sent to the police authorities in all the principal cities in the State of Missouri, I remain, sir, yours, very respectfully,

"'M. WALSHE, M.D.'"

AT a meeting of the Faculty of Jefferson Medical College, Philadelphia, January 14, 1873, the following minute was adopted:

"*Whereas*, The Faculty of the Jefferson Medical College of Philadelphia have heard with profound regret of the death of Dr. Warren Stone, of New Orleans, for upwards of a quarter of a century Professor of Surgery in the University of Louisiana, and for a still longer period the leading surgeon in the Southern States: therefore, be it

"*Resolved*, That they desire thus formally to record the sense of their high appreciation of his talents, and of the loss which the profession and the country have sustained in his demise.

"*Resolved*, That a copy of this preamble and resolution be sent by the Dean of this Faculty to the family of the late Professor Stone, with the assurance of their cordial sympathy in their bereavement."

B. HOWARD RAND,
Dean of Faculty.

THE *Nation*, in a late number, discusses the origin of the word *rickets*, as the name of a disease of children. It would seem to have been in popular use long before Dr. Glisson and some other physicians hit upon the somewhat similar "rachitis." The idea that it was derived from a Dr. Ricketts of Newbury, whose treatment of the disease was very effectual, can hardly be entertained for a moment. A much more probable source of it is quoted from an old writer,—namely, that it is an altered form of "wry-gates," *i.e.*, crooked goings, in allusion, of course, to the distorted hobbling of its victims.

THE classes at the Vienna School of Medicine are said to have fallen off greatly, by reason of the strictness of the examinations. One clinical teacher has no students at all to listen to him. Hyrtl has but four hundred, instead of six hundred as formerly; while Billroth and Arlt have respectively but forty, instead of about three hundred and fifty.

HOSPITAL AT JERUSALEM.—We see it stated that there is at Jerusalem a hospital, or rather, we should judge, a dispensary, under the auspices of the English Society. The institution would seem to be actively engaged in doing good, over seven thousand patients attending during the year, and about five thousand being visited at their homes.

UNITED STATES DISPENSATORY.—A new edition of this work is in preparation, and will be issued in a few months. It will be in accordance with the recent changes in the nomenclature, etc. of the Pharmacopœia.

AFTER many ineffectual efforts, dissections have been legalized in Canada, by a law similar, we believe, to that which obtains in several of our States.

DRS. FORDYCE BARKER and T. Gaillard Thomas, of New York, have been elected to honorary fellowship in the Obstetrical Society of London.

DR. DAVID C. SKERRETT, for many years a practitioner in this city, died recently, at a very advanced age.

M. JACQUEMIN, honorary physician-in-chief of Mazas (the Paris prison ?), died recently, at the age of 77.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending February 15, 1873, were 309; 168 adults, and 141 minors. 9 were of bodies brought from the country; making the mortality of the city 300. Among the causes of death were:

Consumption of the Lungs	68
Other Diseases of the Respiratory Organs	55
Diseases of the Circulatory Apparatus	12
Diseases of the Brain and Nervous System	48
Diseases of the Digestive Apparatus	20
Zymotic Diseases (1 from Smallpox)	19
Typhoid Fever	4
Casualties	8
Cancer	4
Debility (including "Inanition" and "Marasmus")	25
Still-born	14
Old Age	13

(The interments reported for the week ending February 17, 1872, were 467.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER.		BAROMETER.
	Max.	Min.	(2 P.M.)
Feb. 9	32.0°	15.0°	30.13 in.
" 10	24.5	11.5	30.44 in.
" 11	44.0	31.5	30.10 in. (Slight rains.)
" 12	37.0	29.0	29.96 in. (Rain and Snow.)
" 13	32.0	22.0	30.21 in. (Snow.)
" 14	34.0	18.5	30.54 in.
" 15	40.5	24.0	30.63 in.

SATURDAY, MARCH 1, 1873.

ORIGINAL COMMUNICATIONS.

THE MICROSCOPICAL STUDY OF BLOOD AND EPITHELIUM.

A Communication to the Biological and Microscopical Section of the Academy of Natural Sciences.

BY JAMES TYSON, M.D.,

Lecturer on Microscopy and Urinary Chemistry in the University of Pennsylvania; one of the Attending Physicians to the Philadelphia Hospital, etc.

(Continued from page 327.)

IN the nucleated oval corpuscles of the frog and newt, the nucleus comes at first more prominently into view, in contrast with the swollen paler periphery. Later, however, it also becomes swollen, smooth, and fainter.

Rollett, in Stricker's Histology,* calls attention to a structure which becomes developed in the elliptical corpuscles after the cautious addition of water. "The still ellipsoidal corpuscle is bounded by a perfectly smooth contour-line, but the place of the nucleus sometimes appears to be occupied by a colored spheroid, whilst in other cases numerous processes radiate from the ball towards the contour-line, becoming pointed peripherally." These forms, according to Kneuttinger, are obtained when fresh frog's blood from which the fibrin has not been removed is mingled with three or four times its volume of water, and an examination is shortly afterwards made of the resulting gelatinous mass.

In the instance of the colorless corpuscle the addition of water is also attended by some imbibition and swelling of the cell, though this effect is much less marked than in the colored disk. The most marked effect is upon the granular matter and nuclei. According to Rollett,† the granular material contracts "around the nucleus," and only remains "connected with the surrounding parts by means of a few anastomosing processes." Whatever the precise changes may be, the granules finally disappear from the periphery and even close up to the nuclei, which become more distinct by contrast with the surrounding apparently empty space.

The nuclei themselves also at first swell, but finally, after considerable intermediate change of form, shrink up and become actually smaller.

3. The action of *watery vapor* is similar, and is easily practised by affixing a putty ring to a glass slide, and placing a drop of water in the chamber thus formed. The object to be examined is attached to the lower surface of the covering-glass, which is then brought down upon the ring of putty and carefully pressed in position. Some care must be taken in graduating the quantity of water, since, if too much be used, the under surface of the thin glass becomes covered with moisture; and if too little be used, the drop becomes dry before it is influenced by the vapor.

4. The action of *dense solutions*, as of neutral salines which do not precipitate the contents of the corpuscle, such as common salt, sulphate of soda, muriate of ammonia, borax, and others, as well as of simple syrup, should be observed. In consequence of their density, a current is established in the opposite direction from that induced by the water as a rarer fluid; hence the peculiar shape of the red disks is rendered more distinct; they become more biconcave, wrinkled, crenated. In the colorless corpuscles, by the action of these solutions, the nuclei also slowly become more distinct.

5. *Dilute acetic acid*, say a twenty per cent. solution, is a reagent much used. Its action on the human blood-corpuscle is similar to that of water, but very much more rapid. Under its influence the non-nucleated red disk swells up, becomes spherical, and finally loses its color, and, as described in the case of water, becomes almost and in some instances quite invisible.

On the colorless corpuscles, likewise, the action of acetic acid is similar to that described as due to the action of water, but more rapid.

On the nucleated oval corpuscle of the frog and newt acetic acid causes a beautiful staining of the nucleus with the coloring-matter of the blood, while a precipitate is apt to occur in the surrounding colorless substance.

6. *Alkalies* in sufficient concentration exert a solvent action upon both the red and the colorless corpuscles, causing their total disappearance, as is to be expected, since albuminous matter is soluble in alkalies.

In very dilute solutions their action, for the same reason, is not unlike that of acetic acid, swelling up the red corpuscles, making them spherical, and removing the coloring-matter, while in the colorless corpuscles the nuclei become more distinctly defined. In the action of the stronger solutions upon the nucleated oval corpuscles of amphibia, the nuclei are the last to disappear.

7. *Boracic acid*, two per cent. solution, has the same action as acetic on the human blood-corpuscle. On the nucleated oval red disks it has a peculiar influence, first investigated by Brücke. The most conspicuous effect—described by Klein as a "coagulation of the hæmoglobin in the nucleus"—consists in an intense coloration of the latter at the expense of the coloring-matter of the remainder of the corpuscle, which becomes pale or completely colorless. The same is said by Brücke to occur on the addition of a two per cent. solution applied to corpuscles dried on a slide, but has not been repeated by us. Moreover, this effect also occurs when, through the action of water, freezing, or electricity, the corpuscles have yielded up their coloring-matter to the serum, from which the coloring-matter seems again to be precipitated about the nucleus.

The boracic acid solution also, as in the case of water, and acetic and other dilute acids, causes the corpuscle to swell up, become ellipsoidal, and even spherical, the nucleus being often eccentrically situated; while Brücke has even seen the corpuscle discharge its nucleus under the action of this acid.

* New Sydenham Society's ed., vol. i. p. 396.
† Op. cit., vol. i. p. 58.

8. *Tannin*, in two per cent. solution, produces a striking effect on red corpuscles, coagulating the hæmoglobin of the human disk into a knob-like mass. In the oval nucleated corpuscle of the frog a similar effect is produced, but the hæmoglobin is also coagulated about the nucleus, as with boracic acid.

9. Striking and beautiful effects are produced by the action of *carbonic acid*, as first demonstrated by Stricker, and may be studied without difficulty by accurately observing the following plan, derived from Dr. Klein in the Brown Institution, London. If Stricker's gas stage is not at hand, one may be extemporized in the following manner. On an ordinary glass slide is placed a ring of putty; along the middle of the slide, extending from just within the putty wall, and perforating it, to a short distance beyond its edge, is attached a piece of fine glass tubing with a lumen of one-eighth to one-fifth of an inch. The tube is made to project beyond the edges of the slide, in order that a piece of rubber tubing of appropriate calibre may be slipped over it and attached to the gas-producing apparatus. At a point, however, between the edge of the slide and the gas-generator a T-shaped tube is introduced, the horizontal portion of which lies in the axis of communication between the wash-bottle and the slide, whilst the leg of the T is directed towards the observer (see Fig. 2 of the Introduction to Stricker's Histology). To this also is attached a long rubber tube, the end of which is placed between the teeth of the observer. The chamber, being constructed, is attached to the gas-generator of Stricker (see also same cut). The latter consists of a flask of dilute sulphuric acid attached by a rubber tube to another containing small fragments of carbonate of lime, which is in turn connected with a wash-bottle, communicating by means of the rubber and glass tubing with the interior of the gas-chamber. It is evident that the generation of gas may be started or discontinued at pleasure by changing the level of the acid-bottle above or below that of the bottle carrying the carbonate of lime.

The apparatus being thus prepared, to—1. *a small quantity of human blood* on a glass slide is added *a relatively large quantity of the indifferent salt solution*. The two are mixed, and a drop of the mixture is placed on a circle of thin glass, which is then placed drop downwards over the putty ring, the chamber placed on the stage, and watched until the corpuscles begin to appear crenated. The end of the tube between the teeth is closed, and a current of carbonic acid is passed into the cell by simply permitting the access of the acid to the carbonate of lime. *The crenated appearance promptly disappears.*

2. Take a *small* quantity of the blood of the frog or newt, and add a relatively *small* quantity of water, so that the disks become swollen but retain their color. Examine this blood, as before, in the gas-chamber. *No nuclei will be visible.* Allow carbonic acid to enter from the apparatus, and the *nuclei reappear.*

3. To a *small* quantity of the newt's or frog's blood add a relatively *larger* quantity of water than in (2), so that the corpuscles are much swollen but the color remains and the nucleus is visible. On the admission of carbonic acid the hæmoglobin *coagulates in the nucleus, coloring it decidedly.* If now by means of a clip on the gum tube the access of CO_2 be cut off, and the observer aspire through the tube in the mouth communicating with the T-shaped tube, the coloring (hæmoglobin) returns to the body of the disk, leaving the nucleus again uncolored.

4. To a small quantity of newt's blood add a *large* quantity of water, so as to remove all the color from the corpuscles. Then permit the access of CO_2, when a *precipitation of granules of paroglobin takes place* in the substance of the corpuscle. Now let the observer cut off the access of CO_2 by the clip, and aspire through the prolonged T-shaped tube to remove the CO_2, and *the homogeneous colorless appearance of the disk is again restored.*

The preparation of *hæmin-crystals* is a much simpler matter than is commonly supposed. A drop of human blood is placed upon a slide and allowed to dry. A little of this is scraped off, placed upon a second slide, a few particles of common salt added, and covered. Two or three drops of glacial acetic acid are then allowed to pass under the thin glass cover. The slide is heated for a few seconds over a spirit-lamp (until a few air-bubbles appear is sufficient), and examined by the microscope. Hæmin-crystals will be found.

EPITHELIUM.

Ciliated epithelium may be obtained for examination by scraping the back part of the tongue or throat of the frog or toad, and should be examined in the salt solution. Thus mounted, the ciliary movement may be studied for hours.

Ciliary motion having ceased, it may be temporarily restored by the addition of any reagent, as water, solution of potash, acetic acid, carbonic acid, etc. This temporary restoration of the movement is, however, simply the result of currents induced by the liquids thus added, as will be plain a few minutes later, when, coming into *actual contact* with the cells, they *promptly cause cessation of the ciliary movement.*

In a preparation thus made, some cells will be seen to be very much more granular than others. Any cylindrical epithelial cell from mucous surfaces may become thus granular by the addition of water, chromic acid, and other reagents; pressure, and, therefore, accident, may induce them. Certain of these cylindrical epithelial cells thus acted upon by water should be further carefully watched; eventually hyaline spherical knobs appear, apparently coming from the anterior edge of the cell. Finally liberated, they leave the cell whence they are derived, with a concavity, whence it is termed a "goblet cell." These goblet cells are considered by some as peculiar mucus-forming cells; but, for the reason just given,—that any epithelial cell from these sources is liable to take this shape,—they are justly denied by Klein to possess any such special function.

If it is desired to preserve epithelium for study, portions of the fresh tissue may be taken from different localities, as the trachea, tongue, intestine, bladder, etc., and washed in a very dilute solution of chromic acid, say one-eighth to one-fourth per cent. They may then be kept for a long time in a solution of one-eighth per cent. strength, for a longer time in a strength of one-tenth per cent., and if it be desired to keep them for a short time only, a strength of one-half per cent. may be used.

1. Columnar epithelial cells including ciliated cells may be obtained from the trachea of the rabbit.

2. Pavement-epithelium from the tongue of the rabbit, and among these "ragged cells," or "riff cells" (Riefezelle, Stachelzelle).

3. Pavement and club-shaped cells (intermediate forms) from the urinary bladder of the rabbit. The excavated under surface of the former, into which the latter fit by their upper convex extremities, should be noted.

4. Columnar epithelium from the stomach of the rabbit.

5. Columnar epithelium on the villi of the small intestine of the rabbit; the pale striated rim on the free border should be looked for. These striæ, which can only be satisfactorily studied with the higher powers particularly of the immersion system, are generally acknowledged by histologists to be due to delicate porous canals which perforate the seam.

They are best shown in *fresh* preparations from the intestine of cats and dogs, mounted in serum.

6. The epithelium from the fresh intestine of the rabbit should also be examined after feeding the animal, with a view of detecting oil-globules in transit through it.

ANILINE-POISONING FROM A CRIMSON NECK-HANDKERCHIEF.

REPORTED BY JOSEPH G. RICHARDSON, M.D.,

Lecturer on Morbid Anatomy in the University of Pennsylvania; Physician in the Out-Patient Department of the Pennsylvania Hospital, etc.

WITHIN the last few years a number of communications have appeared in one or more of the British medical periodicals in reference to the cutaneous irritation set up by articles of clothing, such as socks, gloves, shirts, etc., colored with aniline, and some of its analogues among the brilliant dyes indirectly obtained from the destructive distillation of coal; but, so far as I am aware, no instances of like nature have hitherto been reported in any of our own medical journals.

Such being the fact, I presume many readers will feel interested in the observations made abroad upon the subject, which are concisely summed up by the editors of the *Medical Times and Gazette* (London, August 7, 1869) in the following remarks:

"The facts known about it are few and striking, but by no means clear. There is no doubt that some persons who have worn silk socks dyed with sundry brilliant colors have suffered from severe irritation of the skin, peculiar redness, vesication, intense pain, and general illness. The affected patches of skin have corresponded exactly with the colored portions of the socks; and of all the colors red and scarlet have proved the most severe in their effects. The socks have been washed and the color has been washed out, but still, we are assured, the irritating qualities have remained."

Again, in commenting upon the report of a committee appointed to investigate the subject, the editors observe, "One gentleman, who was unable to attend to his business (on account of suffering from colored socks), and was absent from home and under medical care for more than six months, is said to have forwarded to the committee a list of eight physicians of eminence whom he consulted, and of whom three pronounced the cause of his illness to be 'poverty of blood;' three called it secondary 'enthetic' disease, spite of the patient's denial that he had ever had primary disease of the kind; one called it indigestion; and one said it was a 'skin affection,' which last diagnosis was indisputable. We need not be too sensitive to the ridicule attaching to such diversities of judgment, but we may take the hint that new causes ought to be suspected and looked for when we meet with new and unusual symptoms."

This description of the facts in aniline-poisoning as noted by English physicians closely accords with the phenomena met with in the case I am about to detail:

J. B., a farmer, 74 years old, residing near Darby, in the vicinity of Philadelphia, came under my care in the out-patient department of the Pennsylvania Hospital, January 27, 1873. His neck, face, and head were much swollen, and displayed an erysipelatous redness, which was accompanied with intense smarting and burning pain, so severe that for more than a month he had been unable (according to his own account) to sleep at night. On investigation I found that the attack had first made its appearance about seven weeks before, in the form of an eruption of "little water blisters" upon the sides of the neck and on the chin below the angles of the mouth, from whence it had spread to the extent above mentioned. Soon after the disorder commenced, he had consulted a neighboring physician, who inquired when he had been in the woods to get poisoned, and had prescribed for him a wash of sugar of lead, from which, however, he derived no benefit. Finding the patient had never been subject to poisoning from Rhus toxicodendron before, and deeming the starting-point of this disease an unusual one for such a malady, I was led to doubt the accuracy of his medical adviser's diagnosis, and on further questioning I learned that two weeks before the affection first appeared he had commenced wearing a silk neck-handkerchief, newly dyed of a crimson color, which I at once requested that he would bring down to the hospital and show me on his next visit. On examining the handkerchief I immediately recognized the brilliant hue of red aniline with which most microscopists are so familiar; but, in order to determine the point beyond all doubt, I tested a small portion of the stuff as recommended by M. Tardieu in his memoir upon the subject, namely, by first boiling the suspected tissue in strong alcohol, when the spirit became of a bright-red color, whilst the fabric was partly bleached in the process, and afterwards by adding ammonia to the tincture thus prepared, which, by rapidly decolorizing the fluid, demonstrated that the cause of all this mischief was aniline, and not coralline.

The treatment consisted in the liberal application, upon soft linen rags, of slippery elm mucilage (which he subsequently stated was the first thing that gave him any relief), and in the administration of a mixture composed of

Morphiæ acet., gr. j;
Spt. ether. nit., f℥ss;
Potass. bromid., ℥j;
Aq. menth. pip., f℥iijss;
Syr. zingiberis, f℥ij,

of which a tablespoonful was given every four hours, as required, to allay the pain, fever, and restlessness at night. Under these remedies the disease rapidly yielded, and on the 10th of February he very gratefully reported himself cured.

The lessons taught by this case seem to be—in the first place, that, in addition to the aniline-poisoning heretofore recorded as occurring upon the hands, feet, and thorax, we are liable to meet with examples of cervical irritation caused by wearing neck-handkerchiefs colored scarlet with this noxious dye; and secondly, that our patients who are supposed to be suffering from the effects of "poison ivy" or "poison sumach" must be carefully questioned not only concerning the ordinary eruptive diseases, but also in regard to possible contact of their integument with fabrics impregnated with the aniline colors, if we wish to avoid mortifying blunders in diagnosis and in treatment.

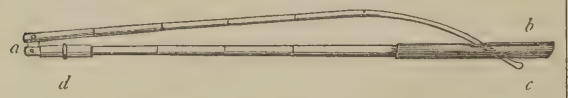
No. 1620 Chestnut Street, February 10, 1873.

A COMPACT UTERINE SOUND.

BY HENRY E. WOODBURY, M.D.

I DESIRE to bring before the profession my modification of the present uterine sound, which renders it far more compact and convenient for carrying in the pocket. My attention was directed to this subject from the fact that, on two different occasions, I lost the long sound from my pocket in going to or coming from my patient's house.

The ordinary long sound is a very formidable-looking instrument to the patient, and liable to be lost by slipping out of the pocket. Both of these objections to it are obviated by my improvement, I think, and the cost of the instrument is not much enhanced.



I have it made with a joint (*a*), hinge-like in character, so that it may be closed after the manner of a pocket-knife, and its length diminished just one-half. When it is folded, the probe-pointed extremity (*c*) is passed through an opening in the handle (*b*), made for the purpose, and thus retained *in situ*. The slide should be about seven-eighths of an inch in order to fix the joint.

To prepare the instrument for use, we disengage the point (*c*) from the opening (*b*), and, straightening the sound, keep it in position by means of the slide (*d*).

I think that this brief description will commend my improved sound to the profession as a far more compact and convenient instrument than that in common use. The ordinary sound may be altered to this form, by introducing the joint and slide, at a small expense.

Charles Fisher, surgical instrument maker, 424 Seventh Street, Washington, D.C., manufactures the improved sound.

Washington, D.C., November 15, 1872.

TRANSLATIONS.

VON OPPOLZER'S LECTURES ON DISEASES OF THE ŒSOPHAGUS.

Being the latter portion of the first part of the second volume of Oppolzer's Vorlesungen über specielle Pathologie und Therapie, Erlangen, 1872.

Condensed from the German of Dr. Emil Ritter von Stoffella,

BY DR. J. SOLIS COHEN.

IV.

DILATATION OF THE ŒSOPHAGUS.

DILATATION of the œsophagus may involve the entire length of the œsophagus, or its greater portion,—*complete or general dilatation;* or it may be partial, confined to a more or less short section, in which case the œsophagus may be dilated in its entire circumference,—*sacculated dilatation;* or one wall only may be dilated, producing a transformation into a circumscribed lateral pouch,—the so-called *diverticulum*. In cases of the latter kind, as a rule, all the coats of the œsophagus are not involved in the dilatation, the pouch consisting of the mucous membrane pushed hernia-like between the muscular fibres, and covered with the external connective-tissue envelopes of the œsophagus.

General and complete dilatation of the œsophagus is usually due to traumatic causes, as a fall or blow upon the back or the breast; or to constriction of the cardiac orifice of the stomach; or to a protracted œsophagitis. Oppolzer has seen it follow the treatment of gout by the copious drinking of warm water. In some cases no ostensible cause can be determined.

Sacculated dilatation of the œsophagus is usually due to constriction of the tube; sometimes to the retention of a foreign body. Occasionally it is observed as a congenital anomaly.

Pouch-like dilatation of the œsophagus, or a *diverticulum*, may be produced by the detention of a foreign body in the folds of the mucous membrane, and the subsequent pressure of this body more and more deeply into the walls of the œsophagus by the food in swallowing, so that it spreads the bundles of muscular fibres asunder and forces the mucous membrane through them in a sort of hernia-like protrusion. Sometimes the diverticulum is produced by the drawing out of the mucous membrane during the shrinking of some previously enlarged tracheal or bronchial glands which have contracted adhesions to the parietes of the œsophagus. In such cases, Rokitansky says, "the glands draw the wall of the œsophagus out into a sort of funnel, from the point of which the muscular investment gradually retreats, so that finally a diverticulum of the mucous membrane is formed, the originally wide orifice of which becomes constricted in consequence of this production of a fleshy margin." Accidents, also, sometimes give origin to the formation of a diverticulum, in the rupture

of some bundles of the œsophageal muscles by a heavy blow, or in their fatty degeneration as a sequel of paralysis following exudation into their substance.

Complete dilatation of the œsophagus, in rare instances, has reached a size sufficient to admit the passage of a man's arm in the interior. General dilatation of the œsophagus is usually connected with muscular hypertrophy, rarely with atrophy of the walls. In many instances there are ulcerations, and even eschars, on the surface of the mucous membrane.

Sacculated dilatation is also usually associated with hypertrophy of the muscular coat. It gradually diminishes in an upward direction, so that a vertical sac is produced, the lower orifice of which is the smaller. If the sacculated dilatation is not due to stenosis, its seat will usually be immediately above the diaphragm.

The diverticulum of the œsophagus is usually formed in the neighborhood of the inferior constrictor muscles of the pharynx, or else in the region of the bifurcation of the trachea, and its position is between the œsophagus and the vertebral column. It communicates with the œsophagus by a round or slit-shaped orifice of variable size. In some cases it draws the œsophagus out of the normal line of its axis, and forms a sort of blind continuation of the gullet, into which the food passes instead of continuing down the tube; so that the patient may become starved to death by this interception of the food on its way to the stomach.

Sometimes several of these dilatations exist, and, if they acquire considerable size, they may, according to Rokitansky, become imbedded in the lungs. Finally, in some instances, a vulnerating body, as a splinter of bone, may become confined in the diverticulum and be productive of inflammation, ulceration, and mortification; the contents of the diverticulum becoming discharged either into the adjacent and adherent lung-tissue, into one of the bronchi, or into the pleural sac; developing pneumonitis, or pleuritis, or mediastinitis, with termination in suppuration, etc.

The *symptoms* of moderate dilatation of the œsophagus, apart from auscultatory phenomena, have nothing marked about them; and, as the condition is usually dependent upon pre-existing stenosis, the symptoms of constriction are those to which attention will be directed in the first instance. If the upper portion of the œsophagus is intact, there will be less difficulty of deglutition than otherwise, because the muscular fibres in this portion of the organ are under the control of the will, and voluntary efforts can therefore still be made to impel the bolus through the dilated portion below.

If there is complete dilatation, there will be no complaint of dysphagia as long as the contractile power of the œsophageal muscles is unimpaired; but if the dilatation leads to paralysis, then deglutition will become more and more difficult, and the dysphagia will finally culminate in utter inability to swallow. If the œsophageal sound be introduced in such a case, it will not strike against any obstacle; on the contrary, in well-marked cases it can be moved about in all directions with great freedom.

Sacculated dilatation of the œsophagus being almost always due to stricture, symptoms of constriction are its most prominent indications. Food remains longer in the œsophagus, and in greater quantity, before regurgitation takes place, than in cases where there is stricture without dilatation. This retention of food, and its partial decomposition, impart a foul odor to the breath. If the dilatation is high up and of considerable dimensions, it may produce a tumor in the neck, visible externally, which enlarges after the entrance of food and drink, and subsides upon the discharge of its contents. If the dilatation exist behind the trachea, it may produce dyspnœa by its pressure; and it may be so situated as to exert compression upon the cervical vessels and thus provoke congestion of the lungs, which, as in Hannay's case,* may suddenly terminate the patient's life by suffocation.

The *auscultatory evidences of dilatation* are, according to Hamburger's researches, as follows. If the œsophagus is only moderately dilated, it is observed that the bolus does not assume the pointed form at its lower portion, but is rounded and broadened off, so that it is rather of the form of an inverted funnel. "If the loss of energy of the fibres increases, the bolus no longer retains its inverted-funnel-shaped form, but is elongated into a trickling stream coursing down the œsophagus. The force of this stream depends upon the condition of the upper third of the œsophagus. If this is healthy, the stream is pretty thick, and it is driven through the diseased lower portion with tolerable rapidity. If the muscular energy in the upper third is impaired, then a slow thread-like trickling is heard. If there are circumscribed but circular enlargements, a sprinkling of the fluid bolus, as it strikes the resistances, is distinctly audible along their entire length, similar to the deflection of rain driven by the wind. By the aid of this sound one can judge of the various dimensions of these dilatations."

The symptoms produced by a diverticulum are, in many respects, similar to those attending the sacculated dilatation. If it exists in the upper part of the neck, and is of considerable size, it may be recognized externally, as a tumor, soft to the touch, reducible to a certain extent by pressure, enlarging after a meal, and subsiding after the subsequent regurgitation. There is also a foul breath, much more offensive than in the other variety, because regurgitation, as a rule, does not take place until twenty-four hours, or longer, after the entrance of food. It may likewise give rise by compression to attacks of dyspnœa, and other disturbances of respiration and circulation. If it have acquired considerable bulk, it may even press laterally against the œsophagus itself to such an extent as to compress its walls to that degree as finally to prevent the passage of food into the stomach. In such cases there is less complaint of dysphagia than there had been previously, because the diverticulum can now contain a greater amount of food. In spite of this relief to the dysphagia, inanition progresses rapidly, and the patient soon dies of marasmus. If the diverticulum is small, and does not enlarge, the life of the affected individual will remain unthreatened, from this cause, for years.

Hamburger had had no opportunity of observing the auscultatory phenomena accompanying a diverticulum up to the time his researches were published; but he expressed the opinion that important aids to diagnosis could be furnished in this way, by noticing the direction taken by the swallowed bolus, and the gurgling which would accompany the entrance of fluid into the diverticulum.

The *diagnosis* of slight degrees of complete dilatation of the œsophagus must rest entirely on auscultation; while, if of considerable dimensions, the introduction of bougies would confirm the diagnosis, for reasons already mentioned.

The diagnosis of sacculated dilatation, in the presence of a stricture, would not be made until the arrival of the period at which food is regurgitated; in addition to which, on ausculting the act of deglutition during the swallowing of a fluid bolus, we should recognize a sprinkling at a circumscribed point. If high up, and

* *Edinburgh Medical and Surgical Journal*, July, 1833.

large, there might be a tumor visible externally. The œsophageal sound is only very seldom of diagnostic value in this form of dilatation, especially when it exists low down.

The diagnosis of a diverticulum, when of moderate size, rests upon the changeable increasing and diminishing pressure on one side of the throat or the other occurring between each meal and its regurgitation. There may also be a tumor externally. If the diverticulum is small or situated low down, there are no evidences of tumor in the neck; there is, however, a characteristic dysphagia which permits the patient to swallow easily and frequently, but is accompanied by a retention of the food at a certain point, and a tendency to rumination; though too much weight must not be given to the rumination, as it may occur under other circumstances. The explorative use of bougies is very important. If the end of the instrument passes through a more or less contracted opening into a cavity which admits of no farther progress of the instrument, there is no doubt as to the diagnosis of diverticulum of the œsophagus. If the sound passes directly into the stomach without meeting with any obstruction, it is no evidence, however, that a diverticulum does not exist, for the instrument may have slipped past the entrance of the diverticulum without engaging in it.

A *differential diagnosis* is necessary to decide between the existence of a sacculated dilatation or a diverticulum, and between either of these conditions and a peri-œsophageal abscess. An error of the latter nature could only occur when the abscess was in the upper portion of the œsophagus, inasmuch as a superficial examination of the tumor in the neck which would be produced by the development of an abscess might lead to its being mistaken for the tumor of a dilatation. Pressure upon the tumor would force pus into the mouth in case of abscess, and mucus and masticated food in case of dilatation. Sacculated dilatations usually follow stricture, and are generally formed immediately above its seat. Therefore a sound, after passing through the dilated portion of the œsophagus, would encounter constriction, which would not be the case with a diverticulum; while, as Hamburger has shown, auscultation would reveal the "sprinkling" within the dilatation on deglutition, an occurrence that cannot take place with a diverticulum.

The *prognosis* depends on the cause of the dilatation and the extent of its development. If the cause is not in itself fatal, and the dilatation is slight and stationary, the life of the patient is in no danger, whether the dilatation be complete, sacculated, or pouch-like. In addition to this, much will depend on the condition of the œsophageal muscles and the position of the dilatation.

TREATMENT.

If the cause of the disease can be remedied, efforts for the removal of the cause would form the most important element in the treatment. In case of a complete dilatation occurring during the course of a chronic œsophagitis, we must endeavor to cure the existing inflammation; or in case of a sacciform dilatation following stenosis, we should treat the stenosis; and so on. Unfortunately, we are rarely able to follow out the causal indications, and must content ourselves with freeing the œsophagus, by the introduction of the sound, whenever that tube is clogged up with ingesta; and nourishing the patient by artificial means, as by the stomach-tube or enemata, when the dysphagia is complete. If a diverticulum exist, it is advisable to administer nourishment through the stomach-tube, and thus prevent accumulation of food in the sac, without waiting until utter inability to force food voluntarily into the stomach has occurred; but it is a proceeding requiring so much resignation on the part of the patient that it is very seldom submitted to, though, by avoiding the enlargement of the dilatation by retention of food in it, it offers the best chance of a cure.

Any direct means of combating the dilatation, at least of the complete and sacciform variety, does not exist in the present state of our scientific knowledge; and the most that we can hope for is to be expected from the use of strychnia and electricity, from the resort to which in cases of complete dilatation of traumatic origin, some direct remedial influence, trifling though it may be, can be reasonably expected.

The diverticulum will probably be rendered amenable to topical measures before the other varieties, because it is usually met with in the cervical portion of the œsophagus, and is therefore more accessible to manipulation. Hamburger has suggested an operative procedure for its removal, without, however, ignoring the danger of pyæmia and descent of pus into the mediastinum during the healing process; but, taking all the attendant difficulties of the operation itself, and the administration of nourishment afterwards, into consideration, Von Oppolzer is of the opinion that it would require no ordinary heroism to incur the responsibility of such an operation.

On Version by the Feet in Cases of Contracted Pelvis (*Centralblatt für die Med. Wiss.*, Dec. 21, 1872; from *Archiv für Gynækol.*, 1872, iv. Heft 2).—S. Borinski gives a résumé of the labors in three hundred and sixty-seven cases of contracted pelvis, observed in the gynæcological clinic at Breslau from August, 1865, to February, 1872, and seeks, by comparing the results of turning with those of all other modes of proceeding, to throw some light on the question of the propriety of that course. The experience at Breslau is against it, since of ninety-three children delivered by version only thirty-four lived; thirty-nine died during or soon after birth (twenty were already dead), nine of whom were killed by perforation; while of three hundred and twenty-two children born by the head only ninety-four died. According to the tables appended, which registered only forty-five cases of version, the relation is the same, the head-presentations having 29.2 per cent., the versions 53.3 per cent. of the dead children. Of the mothers, fifteen died after version, but only three, seemingly, in consequence of the operation. From these statistics the author takes ground against turning as a prophylactic measure, and would limit its employment to urgent and complicated cases. Only in very extraordinary anterior or posterior vertex-positions should it be resorted to. In two cases of asymmetrical pelvis the head passed the shorter diameter easily after turning, while previously it had been arrested in the longer. In repeated deliveries in the same women, changing to head or pelvic presentations, the results were quite contradictory. In prolapse of the cord or of a hand the reposition was generally accomplished with success, only failing once, and even face-presentations came right; while in seven cases of the latter kind in which version was resorted to, five children died.

Extracts in Powder (*Boston Medical and Surgical Journal*).—It is sometimes very desirable to administer the solid extracts (say *extract of hyoscyamus*) in the form of a powder.

All such extracts may be reduced to fine powder by patiently rubbing them (say two or more hours) in a mortar with an equal quantity, by weight, of calcined magnesia.

Extract of gentian yields the slowest to this manipulation.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 1, 1873.

EDITORIAL.

NOT BIGOTRY.

SOME weeks since, we quoted some remarks made by Dr. Cox, formerly a Vice-President of the American Medical Association, at a reception given to the American Institute of Homœopathy in Washington, and expressed the hope that the former body would, at the earliest opportunity, cause his name to be erased from its list of members. The *New York Medical Review*, a journal claiming to "support the fundamental principles of rational eclecticism," thinks that what we said shows "the spirit of bigotry and proscription which actuates and controls most of the institutions and journals of the old or allopathic school." It then goes on to accuse us of denying to homœopathic practitioners any professional rights, and says, "What then is the unpardonable sin that contaminates even by association with them? Why, simply, difference of opinion in therapeutics: that is all. The homœopath thinks an infinitesimal dose of mercury, arsenic, or charcoal sufficient, while the allopath holds to their use in heroic doses."

Perhaps it is hardly worth while to take any notice of statements so easily disproved; and yet we feel as if silence would be construed into admission of the charges. We must say, then, once for all, that no honorable physician would think of treating unprofessionally a man claiming to practise on the homœopathic system, although consultation with him is out of the question. This latter is impossible, since in the first place there is no common ground for them to occupy in discussing any case, and secondly, the Code of Ethics justly says that "no one can be considered as a regular practitioner or a fit associate in consultation, whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession, and of the aids actually furnished by anatomy, physiology, pathology, and organic chemistry." When Dr. C. C. Cox rejoiced to find himself at a meeting of homœopathic doctors, he trampled under foot this just principle,—one of the fundamental laws of the Association of which he had been an officer,—and knowingly violated one of the conditions of his membership in that body. He must have been well aware that he was the guest of those who spared no occasion to vilify and misrepresent the principles and practice of scientific medicine,—of those who in the same breath accuse "allopaths" of bleeding, blistering, and purging patients to death, and complain that they themselves are "ostracized."

The American Medical Association owes it to itself to expel this traitorous member, whose defenders are eclectics,—a fact which strengthens the case against him.

SHALL WE HAVE A CHANGE?

WITHIN three months the annual meeting of the American Medical Association will be held; and as yet we hear no note of preparation towards a change which shall make that body more truly representative of the profession at large in this country, and give it a more authoritative position in regard to the various matters calling for its control. We would again urge the importance—the necessity—of such a change. As long ago as last September, we brought forward the plan proposed by the *Boston Medical and Surgical Journal*, which then, as now, seemed to us to offer great advantages. And we now repeat our appeal to Drs. Gross, Logan, Yandell, Sayre, Davis, and Baldwin, to take the initiative in advocating, before the Association, either this plan or some modification of it. As matters stand at present, there is not a single one of the legitimate objects of such a convention which is accomplished. No other body of men in the United States would be satisfied with such "representation." Let us either have a properly constituted Congress, endued with some powers, and with machinery suitable for their exercise, or let us dispense with the whole concern, abandon all attempt at professional union, and fall behind our age.

A NEW LYING-IN HOSPITAL.

MANY of our readers may be unaware of the existence, in this city, of a State Hospital for Women and Infants, for the benefit of patients in the middle and poorer classes, and of those who would otherwise be compelled to seek refuge in the obstetrical wards of the Almshouse. As yet, this charity is in its embryo stage, having but fifteen beds at its disposal; but it is one which must strongly appeal to every generous heart, and which we believe will meet with abundant and substantial support from the community.

An excellent organization of governors and medical staff has been effected, and a beginning made at No. 1718 Filbert Street. Subscriptions and donations may be sent to Dr. E. L. Duer, Treasurer, 1704 Arch Street, who will also give any desired information as to the plan, etc., of the institution.

CORRESPONDENCE.

THE MEDICAL SCHOOL AT VIENNA.

To the Editor of the Philadelphia Medical Times:

FOREIGN medical schools present strong attractions to the graduate of an American college, from the prominence given in them to clinical teaching; and that university which affords the most extended privileges in this direction will always be visited by the greatest number of strangers.

Vienna possesses peculiar facilities for the practical study of disease, so that its advantages are still predominant even over the lustre of such a name as Virchow's. The seat of the lectures of the University of Vienna is in the General Hospital of that city, situated in the Alservorstadt. It is located on a large square-shaped piece of ground, around and through which the hospital buildings are erected, enclosing in this manner a number of court-yards, or "höfe," that are ornamented with fountains, trees, and flowers. They number perhaps twelve.

The lecture-room of each Professor is situated in the midst of the wards devoted to his peculiar province, which is important in providing for the thorough illustration of his lectures. The courses of instruction given by the Professors, however, less resemble lectures than collections of desultory remarks on the cases that happen to be before them. Professor Sigmund, indeed, delivers his lectures in one of his wards that is filled with patients.

Arrangements are made so that every student may acquire a practical knowledge of parturition in its normal progress and of the accidents to which it is liable. In Prof. Carl Braun's wards there are four thousand births annually. When labor commences, the patient is transferred to the parturient ward, where twelve students, who are changed daily, are in attendance. They are under the supervision of three midwives. If the student have taken five weeks' practical instruction with Prof. Braun's first assistant, he is privileged to perform any of the operations that a difficult or impossible labor may require.

Prof. Meynert delivers an excellent course of lectures on nervous diseases and mental disorders at the Asylum for the Insane, a short distance from the General Hospital. He is more systematic in his course than most of the other Professors, rather illustrating his lectures by cases than attaching remarks in a hap-hazard way to the cases that are at hand.

Prof. Hebra's wards form a complete museum of skin-diseases.

A peculiarity of this university is the number of its private courses. They are given, generally, by the assistants to the Professors. These private teachers, or "Docenten," as they are called, form an important part of the university, and they have their names and other information concerning them embodied in the official catalogue issued at the commencement of every semester. Of these there are two yearly. One commences about the middle of April and ends in the early part of July, the other commences in October and ends in the following February. The energetic private courses continue, however, during the vacations. A private course lasts from four to six weeks, and, after terminating, in most cases immediately recommences. The subjects treated of embrace every branch of medical knowledge. The following list has been deeply impressed on my mind by an earnest study of the hieroglyphs on the bulletin-board at the entrance of the hospital: laryngoscopy and rhinoscopy, the use of the ophthalmoscope, diseases of the eye, diseases of the ear, nervous diseases, medical electricity, the use of the microscope, skin-diseases, percussion and auscultation, diseases of children, general pathology, surgical operations, urinary sediments chemically and microscopically considered. All of these subjects, and others, are exemplified with a copiousness of illustration to which we are strangers. By the concentration within the walls of the same building, of all these subjects of information, time may be economized, so that every hour in the day, from seven in the morning until seven in the evening, may be profitably employed.

In general pathology, however, this school is far behind that of Berlin. Prof. Rokitansky, who still holds this chair, has such an indistinct delivery that it is impossible for foreigners to follow him.

The opportunity that exists in Berlin, for combining Prof. Virchow's theoretical instruction with the practical study of morbid specimens, confers great advantages on this university in the teaching of general pathology.

For the study of the specialties, or for acquiring a practical acquaintance with general medicine, the University of Vienna, from its numerous private courses and its convenience of location, affords unequalled advantages.

In addition to the above-mentioned opportunities for

study, students are allowed to make the morning and evening visits with the Professors, if they choose. Few, however, avail themselves of this privilege; for without it enough cases are seen.

Students must, perforce, conform to the Vienna mode of life. Every one dines and sups at a restaurant. Breakfast is generally taken in one's own room. This meal, contrary to the American custom, is a very light one, consisting, for a well-regulated "Wiener," of a "mélange," a mixture of coffee and milk, and a breakfast-roll. An egg or two is an allowable addition. Any one on one hundred dollars a month can live comfortably and pay all his college expenses, if he has a mind so to do; and in six months, provided he already possesses a reasonable knowledge of German, he can acquire a most gratifying amount of practical information and manual skill in the employment of the instruments of the specialists.

The application of the above remarks on expense will be annulled during the great "Welt-ausstellung" that takes place this year.

It is said, on good authority, that the summer course of the university will be omitted this year, for such a great increase is anticipated in the rent of rooms and in the cost of the necessities of life as to place them beyond the reach of the average German student.

Every "Wiener" intends to make his fortune out of the crowd of Americans and English who are expected to fill the city during the exposition.

Abel F. Price, M.D.,
Assistant-Surgeon U.S.N.

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

February 3, 1873.

Director W. S. W. Ruschenberger, M.D., in the chair.

Present—Drs. Tyson, I. Norris, J. G. Hunt, W. L. Wells, Holt, McQuillen, B. H. Coates, and Richardson, and Mr. Corlies.

Dr. James Tyson read a paper on the "Microscopic Study of Blood and Epithelium," giving full details of the methods now employed in England and on the continent for the investigation of these important structures, and illustrated by experiments demonstrating the mode of producing hæmin-crystals.

Dr. J. G. Hunt remarked that, although this sanguinary subject had been troubling the minds of physicians for some two hundred years, it was probable that even now some of the gentlemen present would not be able to agree with others in regard to the structure of the blood-corpuscles. In difficulty and comparative inutility it somewhat resembled the much-vexed Diatom question; and yet he, the speaker, must plead guilty of having spent some time in these investigations. Quite recently, in examining the blood of a frog, he had seen the nucleus (which, by the way, is a post-mortem change, and never seen in living corpuscles whilst circulating in the vascular system of the reptile) make its way through the protoplasm of the disk, and migrate some distance beyond the margin of the latter, when it appeared under a power of one thousand diameters to be surrounded by a homogeneous vesicle about the size and shape of the rounded corpuscle from which it seemed to escape. This delicate vesicle was so very hyaline that even with a high power it required the most careful manipulation of light for its satisfactory demonstration. At the conclusion of his remarks Dr. Hunt exhibited and compared the absorption bands produced in the spectrum by blood, a solution of magenta, and one of chlorophyll.

On motion, Dr. Tyson's paper was referred to a committee composed of Drs. J. G. Hunt, Isaac Norris, and Richardson.

Dr. J. G. Richardson observed that there was one point in his friend Dr. Tyson's excellent paper which did not fully accord with the results of his own investigations, and that was the statement that the red blood-corpuscles finally disappear when acted upon by water. In certain experiments undertaken some years since in order to test the assertion of Prof. Beale that the red blood-globules are homogeneous drops of jelly-like matter, he had allowed ten drops of blood from his finger to fall into two fluidounces of pure water, and, after stirring up the mixture, had found at the end of twelve hours, at the bottom of the vessel, a whitish flocculent deposit, which under a high magnifying power was seen to be composed of red corpuscles decolorized and rendered spherical by the action of the aqueous fluid. These continued visible for three days, at the end of which time they became obscured by the development of Bacteria; but at a subsequent period he repeated the experiments, slightly altered to prevent the disturbance of the investigation by the growth of fungi. This modification consisted in adding to the water employed a small quantity of carbolic acid, under the influence of which the liquid was preserved free from fungi, and the decolorized corpuscles were distinctly visible, almost unaltered, at the conclusion of thirty days; so that it could hardly be said that they disappeared under the action of water, at least in this instance.

Dr. J. H. McQuillen mentioned that he had observed the appearances, in frog's blood under the influence of alcohol, ether, etc., as described by Dr. Hunt, as long ago as 1868, and in examining recently some specimens mounted at that time he had been pleased to find that the corpuscles retained their shape and general characters in a good degree. He had never been able to detect in human blood the change from a biconcave to a biconvex shape, said by Mülder to occur in the de-arterialization of the blood, and to be the cause of the alteration of color from a bright red to a dark purple hue. He would like to inquire whether the recent improvements in the micro-spectroscope enabled us to absolutely distinguish venous from arterial blood, and also what acceptance Prof. Beale's views of the homogeneous nature of the red blood-corpuscles received from the histologists of Germany.

Dr. Hunt stated in regard to the form of the human red blood-disks that he had repeatedly examined them as opaque objects under a power of one thousand diameters when illuminated by Wenham's truncated parabola, which rendered them distinctly visible, but deprived them entirely of all appearance of a biconcave shape.

Dr. W. Lehman Wells suggested that, in order to test the asserted biconvexity of the corpuscles in venous blood, that fluid should be removed, and preserved during the entire examination, in an atmosphere of carbonic acid, since the oxygen of the air would almost immediately alter their outline, and thus vitiate the results of the experiment, unless precautions against its access were employed.

Dr. Tyson observed that Brücke and Stricker admit

the presence, in the human red blood-disk, of two different substances, which they denominate respectively oekoid and zooid; the former of these two constituents being a frame-work which does not really dissolve in water, but becomes invisible to low powers and any but very careful illumination; whilst the latter is freely soluble in water in all proportions. As to the doctrine of the vesicular nature of the corpuscles, he thought it was disputed by most German histologists of the present day. In reply to Dr. McQuillen, he remarked that he had always doubted the hypothesis of Mülder, on account of his repeated failure to detect any foundation for it on microscopic examination, and he thought the change in hue was now much more satisfactorily explained by Stokes, who has recently demonstrated by the micro-spectroscope that we can produce from the purple cruorine of venous blood the scarlet tinge of the arterial fluid by more highly oxidating this coloring-material, and conversely reproduce the dark tint of the venous current by deoxidating the cruorine.

Dr. RICHARDSON stated that although the micro-spectroscope was undoubtedly the most delicate test for blood, yet, since it afforded no clue to the animal from which the blood was derived, he thought that for the purpose of distinguishing blood-stains in criminal trials an investigation of the size and shape of the corpuscles with high powers was practically much more valuable, especially as he had shown that the corpuscles of human blood could be discriminated from those of most of the animals used for food, such as the sheep, ox, and pig, in a particle of dried blood-clot not weighing over $\frac{1}{12000}$ of a grain (see *American Journal of the Medical Sciences*, July, 1869).

Dr. TYSON asked whether testimony respecting the size of the corpuscles, founded upon observations made on such an extremely minute fragment of blood-clot, would be accepted in a court of law.

Dr. RICHARDSON answered that if there was any difficulty about a case on that score he thought he could take his microscope into court and satisfactorily demonstrate to an intelligent jury the obvious differences which exist between the average diameter of the corpuscles of an ox, a sheep, and a human being, when sufficiently magnified with a powerful objective.

Dr. HUNT thought that such variations in the size of the red globules occur in individual specimens of blood that he would not feel justified in testifying to the origin of the fluid from the measurement of its colored disks.

Dr. RICHARDSON replied that although a few corpuscles in each specimen of blood did vary from the average diameter of their companions, yet when proper precautions against the evaporation of the liquor sanguinis were used, the large majority of the red disks (ninety-eight or ninety-nine out of a hundred) were so uniform in magnitude that practically he had found these comparatively rare deviations from a standard size not to embarrass the investigation.

Dr. HUNT remarked that, whilst the examination of blood-stains might occasionally be useful in murder-trials, most of our researches into the microscopic appearances of blood as well as other tissues of the body were valueless because made upon structures altered, perhaps utterly changed, by death. Hence all our so-called histological investigations were only pathological ones, and taught us absolutely nothing of the powers and properties and processes of living bodies. He believed that the finding of some method to bridge over the *hiatus* between our knowledge of dead blood, for example, and our knowledge of the nature of blood alive in its vessels, was a grand desideratum which still remained to be accomplished.

Dr. TYSON replied that he had no doubt all these various researches would ultimately prove useful, although we could not at present see any direct advantages accruing from the expenditure of time upon them. The beautiful vegetable specimens of Dr. Hunt were undoubtedly of dead matter, and yet, thanks to his laborious and pains-taking modes of preparation, they gave every one clear ideas of the structures under investigation.

Dr. RICHARDSON added that it seemed to him that a first and most important span of this desirable bridge over the hiatus complained of by his friend Dr. Hunt, had been thrown by Prof. Cohnheim in his famous experiment upon the mesentery of a curarized frog, during which the white blood-corpuscles can be seen to accumulate on the inner surface of the smaller blood-vessels when a partial stasis of the blood-stream occurs as the first step of inflammation, and then gradually work their way by their amœboid movement, doubtless, through the stomata between the endothelial cells, until they appear outside the vascular walls, when they constitute, in part at least, the leucocytes of pus.

Dr. HUNT admitted that the experiment last referred to was an investigation upon living blood in its living tissues; and exhibited a very ingenious improvement of the deep glass cell for holding small fish, tadpoles, etc., during examination.

REVIEWS AND BOOK NOTICES.

A HANDBOOK OF POST-MORTEM EXAMINATIONS AND OF MORBID ANATOMY. By FRANCIS DELAFIELD, M.D., Curator to Bellevue Hospital, Pathologist to the Roosevelt Hospital, etc. New York, William Wood & Co., 1872.

A treatise of this kind, to be complete, must cover a great deal of ground. The volume before us does not claim to be exhaustive, but "is intended to serve as a guide for those persons who may be called upon to perform post-mortem examinations. For most physicians this call is only an occasional one: so they may feel the need of some handbook to which they may refer." It strikes us, however, that such physicians require more minute and detailed directions for their guidance in making these investigations than they will find in this volume, and as a book of reference on pathology it is not sufficiently thorough and complete.

For example, in the directions for opening the skull we are told to "make a circular incision from a point three and a half inches above the root of the nose, behind to the occipital protuberance." No instructions are given for preventing displacement of the calvarium when it has been restored to its position after the examination is concluded. This displacement is almost sure to occur when a circular cut has been made, and the deformity thus caused is very objectionable to the friends of the deceased. The plan adopted abroad of inserting small brads into the diploë keeps the parts in perfect and firm apposition.

It is advised to immerse eyes, as soon as removed, in "Müller's fluid;" but what the composition of this preservative is, the physician is left to find out from some other source.*

No mention is made of emphysema of the liver, which, although a rare lesion, has been sufficiently often met with to make one expect to find some allusion to it here. Frerichs, in his work on Diseases of the Liver (Syd. Soc. translation, vol. ii. p. 369), has written a chapter on the subject, and in the number of this journal for October 5, 1872, there is a lecture, by Dr. J.

* The formula for Müller's fluid is as follows: R Potassæ Bichromat. gr. lxxv., Sodæ Sulphat. gr. xxv., Aquæ fld. oz. vi. M.

Forsyth Meigs, on a case in which this lesion occurred in the course of typhoid fever.

The work is divided into four sections. The first gives the method of examining the bodies of adults and new-born children, and includes a brief description of the anatomy of the internal organs.

The second part is a general consideration of morbid anatomy, and occupies the greater portion of the book.

The third part gives the lesions found in some of the general diseases, as typhoid and typhus fever, sunstroke, pyæmia, etc., the lesions after drowning, poisoning, suffocation, and other forms of violent death.

We may remark here that there is no statement made as to the condition of the heart after death from sunstroke. Observers have differed on this point: one of the latest, Dr. H. C. Wood, found the heart rigidly contracted, while others have stated that it is flabby and dilated, after death from this disease. The fact seems to be that the condition of the heart depends upon the length of time after death that the examination has been made, the organ being at first contracted, but after a few hours becoming relaxed.

The fourth section treats of tumors, in the classification of which the author follows Virchow, as do most of the pathologists of the present day.

As a whole, the book is good, being concise and accurate; and, although we have felt called upon to point out some of the deficiencies we have noticed, it is evident that the author is thoroughly conversant with his subject, and has compiled a work that will be useful and convenient to many. The portion relating to new growths in the different organs has been particularly well done. The value of the work would have been greatly increased by references to authorities.

The Practice of Surgery. By Thomas Bryant, F.R.C.S., Surgeon to Guy's Hospital. With Five Hundred and Seven Illustrations. 8vo, pp. 984. Philadelphia, Henry C. Lea, 1873.

In his preface, the author says that the London publishers (Messrs. J. & A. Churchill) invited him to write a work on the Practice of Surgery, "under the impression that there was room for a new text-book on the subject." And no doubt not only did they know the existing state of their market, but the shrewd republisher in this country was equally well aware that his enterprise would be rewarded. This might seem strange to non-professional persons, who cannot be familiar with the many phases in which medicine and surgery present themselves to the experience of different men. Mr. Bryant's book gives the results of his many years' service as surgeon at one of the largest London hospitals, and as such is a valuable addition to our literature. His title seems to us somewhat inadequate, as he has embodied much of the theory of the science with his practical instructions.

We cannot, in the space at our command, go into anything like an analysis of this work. An examination of it has convinced us of its practical character, and of the wide range of its author's reading; while a merely superficial glance would perceive the many new and good illustrations and the handsome mechanical execution, which enhance its claims upon our favor.

Some specimens of careless writing we cannot but note. Thus, in regard to scalds of the larynx, it is said that "this somewhat common accident is doubtless engendered amongst the poor by the habit of feeding their children out of a teapot." Again, in speaking of tracheotomy, "As the result of hurry, many are the mistakes that might be enumerated, such as wounding of the innominate or carotid artery, the opening of the œsophagus through the trachea, the puncturing of the spine through both these tubes," etc. We should say these "mistakes" were due either to flurry,—a different thing from hurry, and a far worse,—or to want of anatomical knowledge or of practice on the dead subject. Again, two lines farther on, "the different points in the neck are then to be made out, and the presence of any large vein in the line of incision looked for, and if present avoided."

These are but minor faults. We take graver exception to our author's use of the term *chancre* for all primary venereal sores; thinking that the soft sore is far better named *chancroid*, and that for practical purposes the making of an "intermediate class" of sores is unnecessary, while it is confusing to the student.

Upon the whole, and we repeat it because we think Mr. Bryant has met with rather harsh treatment from some of his reviewers, this book may be looked upon as a decidedly valuable contribution to surgical literature. It bears evidences of honesty and conscientiousness in its preparation, and of a basis of intelligent practical experience, which should secure it at least respectful criticism.

Fistula, Hæmorrhoids, Painful Ulcer, Stricture, Prolapsus, and other Diseases of the Rectum, their Diagnosis and Treatment. By William Allingham, F.R.C.S. Eng.; Surgeon to St. Mark's Hospital for Fistula, etc.; Late Surgeon to the Great Northern Hospital. Second Edition. Small 8vo, pp. 265. Lindsay & Blakiston, Philadelphia, 1873.

We have been most favorably impressed by this book, having derived both profit and pleasure from its perusal, although its author apologizes for his rough style and his inability to write elegant English, in a preface which is attractive from its mere simplicity and earnestness.

A man may write well on scientific subjects, but hide his individuality under so thick a veil of formally constructed sentences that we have no acquaintance with him as a man, though we may fully understand his views upon the subjects of which he treats. This is too much the fashion of the day; and yet we think that those books will be longest read, even in medicine, which are less apathetically scientific and permit us to feel interest in the characters of their authors. We have been led into this digression by the freshness and energy of Mr. Allingham's preface, and must now speak of the book itself.

In the first chapter, our author treats of the best method of examining the rectum, for which object the lateral decubitus is recommended. We are told that in women, under the influence of an anæsthetic, it is possible, and in some cases advisable, to introduce the whole hand within the rectum and so investigate the state of the parts even up to the sigmoid flexure. The author adds that to do this a small hand is desirable, but does not inform us how a large-limbed surgeon is to obtain such a desideratum.

We would direct especial attention to the chapters upon fistula and hæmorrhoids, and to the method of plugging the rectum for secondary hemorrhage after operations upon the latter, as particularly valuable, and indicative of that thoroughness of treatment in the attention to practical details which appears to be one of the great merits of this author.

Mr. Allingham advocates a free incision in cases of fissure of the anus, as less liable in his experience to be followed by relapse than is the case when the sphincter is forcibly dilated or but superficially incised. He also narrates a few cases, which have occurred in his large experience, where a cure has been accomplished by the use of stimulating and sedative ointments combined with careful general treatment. Such cases must certainly be regarded as very rare exceptions to the rule.

In speaking of the fæcal accumulations which occur in the rectum, and the vast amounts which sometimes

come away, our author (p. 230) says he has seen "two or three chamber-utensils passed at one operation," which, to say the least, is very surprising! We presume it was, as an Irishman would say, "the full of two or three pots." Why is not pot as good a word as utensil, vessel, pot-de-chambre, *et id omne genus?* Why should we emasculate our mother-tongue, and cease to use a good, short, native word, substituting an inaccurate, long, foreign hybrid in its place?

While we might venture to differ with Mr. Allingham upon some minor points, we should do so with great diffidence in the face of the experience he has enjoyed, and the table of four thousand cases upon which his book is based. And we have no hesitation in saying that we regard this eminently practical book as one of the most valuable contributions to the stock of knowledge of rectal diseases with which we are acquainted, and as one which no practitioner at all interested in the subject can afford to be without. That this is also the verdict of the profession is evidenced by so early a call for a second edition, which is issued by the American publishers in a very neat and attractive form.

A Handbook of Therapeutics. By Sydney Ringer, M.D., Professor of Therapeutics in University College, Physician to University College Hospital. Third Edition. 12mo, pp. 576. New York, William Wood & Co., 1872.

The demand for a third edition of this work is evidence enough of the popularity which it has gained. It is a handy-book of reference with regard to the therapeutic qualities of most of the articles in the British Materia Medica; arranged, however, in a very unscientific manner, commencing with oxygen, water, peroxide of hydrogen, and continuing through the list of chemical agents, some of which are partially classified in groups; after which follow substances of animal and vegetable origin, some of a class sometimes in rotation, and sometimes not. Then there is a posological table from Dr. Garrod's Materia Medica; a dietary for invalids, containing some excellent receipts; an index of medicines, and an index of remedies. Without the two indexes one would be in a great quandary to discover in what portion of the book he might find the information he wanted; but, as they are quite full, they render the work convenient for reference.

Certain subjects, such as digitalis, belladonna, opium, and a few others, are discussed with a tolerable amount of detail; and some others, including nitrite of amyl, hydrate of chloral, physostigma, and carbolic acid, have fair consideration. The views expressed are in the main sound, and the facts reliable; but different subjects are occasionally interpolated, or brought into line in foot-notes in a manner to worry a methodical reader. The object of the work is excellent, and the fund of information it contains exceedingly valuable; but we think that if the author had only taken time to elaborate his matter in some more systematic manner, it would have been of much greater practical value. The style of composition is curt,—sometimes loose; long sentences are comparatively rare; the language is plain and rarely mistakable. Take the book all in all, it is a very good one in spite of its faults, and, like a ready-reckoner to the overworked accountant, will be found—barring too many typographical errors—a useful handbook for the busy practitioner. ***

The Philadelphia Medical Register and Directory. Edited by John H. Packard, M.D., Secretary of the College of Physicians of Philadelphia. Third Edition. 12mo, pp. 304. Philadelphia, Collins, 1873.

We gladly welcome the new issue of this little volume, which, while almost essential to the comfort of physicians practising in Philadelphia, contains much of interest to the profession at large, in the shape of condensed and official information about the many charitable institutions in which we feel a pardonable pride.

As in all books of the kind, errors have crept into this directory; but we cannot feel surprised at what appears to be necessarily incident to such an undertaking. This state of things will never be corrected until, in addition to the thorough system adopted of inquiries both by mail and canvassers, the profession in Philadelphia resolve upon a hearty and pains-taking co-operation with the editor in his labors. We regret to see that Dr. Packard has restricted his mortuary list to the city of Philadelphia, discontinuing the more extended series begun in the last edition, and that greater fulness has not been attained in this narrowed field. It appears to be superfluous to add more concerning a book so well known, and read of all men. We would only urge upon all, whose office-tables are not furnished with this little volume, the wisdom of providing themselves with a copy at their earliest opportunity.

BOOKS AND PAMPHLETS RECEIVED.

Medical Essays: Compiled from Reports to the Bureau of Medicine and Surgery, by Medical Officers of the U.S. Navy. Published by Order of the Navy Department. 8vo, pp. 367. Washington, 1873.

Burns and Scalds: Their Treatment, with Cases. Read before the Sacramento Society for Medical Improvement, January, 1872. By Joseph F. Montgomery, M.D. 8vo, pp. 24.

Ophthalmic and Aural Surgery Reports. By Julian J. Chisolm, M.D., etc. (Reprinted from the *Richmond and Louisville Medical Journal.*) 8vo, pp. 24. Louisville, 1873.

Eighteenth Annual Report of the Southern Ohio Lunatic Asylum, at Dayton, Ohio. By S. J. F. Miller, M.D., Superintendent. 8vo, pp. 43. Columbus, 1873.

Annual Report of the Mississippi State Lunatic Asylum for the Year 1872. By William M. Compton, M.D., Superintendent. 8vo, pp. 52. Jackson, 1873.

Geological Survey of Pennsylvania. By Prof. J. P. Lesley. 8vo, pp. 12, 1873.

GLEANINGS FROM OUR EXCHANGES.

Traumatic Rupture of the Urethra; Puncture of the Bladder above the Pubes; External Urethrotomy; Cure.—*Le Mouvement Médical* of August 31, 1872, gives the following résumé of a case reported in *L'Union Médicale* by Dr. Bousseau:

F., 52 years of age, received on the 13th of last February a kick on the scrotum. Immediately after the receipt of the injury, blood passed from the urethra, and continued to do so for six or seven days; this hemorrhage did not cease entirely until twelve days subsequently. Three weeks afterwards, urine could only be voided in drops and with effort. Rupture of the urethra and contraction from cicatricial tissue had evidently occurred.

The patient was admitted into the Hôpital de Cholet on the 29th of March. The bladder was distended above the pubes, and the most powerful straining resulted only in the expulsion of a few drops of urine. M. Bousseau tried in vain for six days to pass the

stricture with filiform bougies, and then decided to perform the operation of external urethrotomy.

The operation was done with the assistance of Drs. Maudet, Cancalon, and Lorin. When the patient was placed in the required position, a grooved sound was introduced into the urethra as far as the anterior part of the stricture, and an incision was made in the perineum down to the extremity of the instrument. The lips of the wound being held apart, the surgeon endeavored to find the canal, but the search was attended with negative results. The incision was extended, but it was impossible to find the urethra. M. Bousseau then abandoned the first operation, punctured the bladder above the pubes, and fixed a gum catheter in the wound. The condition appeared most critical.

Four days after the performance of this operation the surgeon introduced a metallic sound with a large curvature into the bladder through the wound in the hypogastrium. The index-finger introduced into the wound served as a guide for the discovery of the neck and the extremity of the sound. There only remained about a centimetre (one-third inch) of fibrous tissue to divide in order to expose the sound. An elastic catheter was afterwards introduced into the urethra through the penis, and was made to come out in the perineum. It soon became possible to pass the catheter into the bladder and to fix it in position. No symptoms of any consequence ensued; the hypogastric fistula closed in four or five days, and the urine soon took its normal course.

M. Bousseau has undoubtedly given proof of his dexterity, and his efforts have been crowned with success.

The case shows us how difficult it is to perform the operation of urethrotomy without a guide. Would it not be more prudent, as M. de Méric of London has remarked, to puncture at once the bladder through the rectum, and to leave the re-establishment of the normal course of the urine to further procedures?

Could not the bladder be emptied by a capillary trochar, assisted by the aspirator, an operation which has been shown to be trifling in character?

Chloral-Urea—its Influence upon the Animal Organism (Langaard: quoted from *Centralblatt für Med. Wiss.*, No. 42, 1872).—At the suggestion of O. Liebreich, Langaard has investigated the assertion of Jacobsen concerning the union of chloral with urea. There are two forms: one almost insoluble in water and alcohol, but easily soluble by heat; the other, even in boiling water, almost insoluble. The first is represented by the formula (C_2HCl_3O, CoH_4N_2;) the second by ($[C_2HCl_3O]_2\,CoH_4N_2$). Both of these are decomposed by alkalies—but more slowly than chloral hydrate, especially the insoluble form—into chloroform, formates, ammonia, and carbonates; the insoluble form, however, may remain in a strong solution of potash for hours, at the ordinary temperature of a room, without being completely decomposed.

Small doses administered by the stomach, in quantities varying from 0.5 to 0.75 gramme, have scarcely any hypnotic influence. Equal or somewhat greater doses, administered hypodermically, have a hypnotic influence in about one hour. Larger doses (2.5 grammes) injected gradually into the stomach produce very apparent drowsiness without anæsthesia, but have proved fatal, with symptoms of slow pulse and irregular respiration. Post-mortem examination showed the left ventricle to be almost empty, and the right ventricle distended at the vestibule; in the urine of the bladder chloral-urea was detected. Two-gramme doses in solution introduced into the stomach produce, in about one hour, long-continuing sleep. Anæsthesia accompanying sleep is produced by the introduction of the fatal dose of four grammes into the stomach. In such cases anæsthesia occurs in half an hour, and death in seven hours. Both ventricles are then found dilated, and in the bladder a little urine is discovered which contains principally chloroform. The hypnotic effect of small subcutaneous doses (0.5 gramme) may be accelerated by the introduction of two grammes of carbonate of soda into the stomach one hour before they are administered, sleep without anæsthesia being produced in fifteen minutes. If in the same animal the injections are continued, so that in two hours it receives two grammes of chloral-urea, anæsthesia is soon perceived, and at the same time irregularity and weakness of the heart ensue, and its action ceases in thirty hours. In these cases the post-mortem examination revealed a dilatation of the ventricles and vestibules. In the scanty urine of the bladder neither chloral-urea nor chloroform could be detected. The insoluble modification works with much less intensity in the presence of an alkaline solution than the one already described.

Enlargement of the Cervical Glands disappearing during an Attack of Erysipelas (*Le Mouvement Médical*, November 16, 1872).—N., 74 years of age, was admitted into the Hôpital Saint-Antoine (service of M. S. Fereol) on the 6th of July. In April, after an attack of deafness, the patient observed an enlargement of two glands on one side of his neck, and afterwards on the other. They increased rapidly in size, and soon the neck appeared to be continuous with the thorax. Œdema followed, but it was confined to one side of the neck. Attacks of hæmoptysis occurred, and were attributed to the presence of varicose veins in the œsophagus and trachea, a diagnosis rendered still more probable by the existence of enlargement of the veins at the base of the tongue. The circumference of the neck varied between 50 and 53 centimetres. During the last days of the patient's life, before the occurrence of the fatal complication, it had attained 57 centimetres. Erysipelas of the right arm developed and rapidly assumed a gangrenous form. Two days after its onset it was observed that the enlargement of the glands had almost entirely disappeared. The patient died two or three days after the occurrence of the erysipelas.

The glands were found, at the autopsy, to be less voluminous than when observed during life, but of greater size, however, than was anticipated. On opening the internal jugular vein, two tumors were found; they were of the size of a bean, and were continuous with the external tumors. The calibre of the vein was obliterated by them.

The glandular tumors were slightly adherent to the skin, which was itself somewhat attenuated. Section of the skin of the arm revealed œdema of the cellular tissue, and the presence of small tumors, which, when enucleated, left small cavities behind. Examination of the blood did not show any increase in the proportion of the white disks.

According to M. Castiaux, the skin is not adherent in simple adenitis. M. Malassez, however, states that this does not always occur, for he has found the skin in some cases very tightly adherent to the tumors, and even ulcerated.

Aneurism of the Left Vertebral Artery—Rupture—Gradual Hemorrhage beneath the Meninges (by A. Sevestre: *Le Mouvement Médical*, October 12, 1872).—A man, 45 years of age, after an indescribable attack of sickness, was taken in the early part of September with cephalalgia and lumbar pain. During the first twelve days of his illness he was able to attend to his work.

Finally, a second attack occurred, and was followed by paraplegia. Two days afterwards the power of

motion was partly restored, and when the patient came under the care of M. Jaccoud, in the Hôpital Lariboisière, paresis alone remained. The patient was able, with some difficulty, to stand erect. The urine contained neither albumen nor sugar. The heart-sounds were normal. On inquiring into the previous history of the patient, it was found that he had had a chronic urethritis, accompanied by sore throat, and an eruption upon the body. The diagnosis, based principally upon these latter phenomena, was that of cerebral tumor of syphilitic origin, and a tumor, probably, of the spinal cord in the lumbar region. The patient was treated with the iodide of potassium.

Other attacks ensued, and on the 27th of September there occurred a marked amelioration of the symptoms, the patient being able to get out of bed and walk about. On this same day a new attack carried him off suddenly. At the autopsy, blood was found effused beneath the membranes at the base of the brain and into the fourth ventricle; hemorrhage had also occurred around the dorsal and lumbar portions of the cord. The cause of the hemorrhage was the rupture of a sacciform aneurism of the left vertebral artery.

A hasty examination failed to reveal the presence of other aneurisms, either in the brain or membranes of the cord. There was no atheromatous degeneration of the vessels. M. Sevestre thinks, from the course of the symptoms, that the hemorrhage occurred gradually. The sudden death may be explained by the effusion of blood into the fourth ventricle.

Inflammation of the Penis (by M. Demarquay: *Le Mouvement Médical*, August 31, 1872).—Suppuration of the corpora cavernosa is of very rare occurrence: hence the following case, communicated by M. Demarquay to the Chirurgical Society, is of practical and scientific interest. X., 38 years of age, was admitted into the Maison de Santé on the 17th of April, 1872. He was a man with a constitution impaired by four attacks of acute blennorrhagia, the last one having occurred seven years previously. Several weeks before his admission the patient was taken with retention of urine and tenesmus, and at the same time a small tumor formed in the perineum in front of the anus. It suppurated, and was incised; but subsequently a swelling occurred behind the bulb. M. Demarquay diagnosticated an abscess originating in the glands of Cowper. The parts involved were freely incised, but complete cicatrization did not take place, and urine occasionally escaped from the wound. On the 1st of June the skin of the inferior surface of the penis became red, tender, and painful, and on the 5th the organ had increased to an enormous size, and looked as if it was in a state of erection. The sensation imparted to the touch was that of hardness rather than of puffiness; pressure caused a moderate amount of pain. M. Demarquay made the diagnosis of inflammation of the penis.

General symptoms of a very grave character occurred two days subsequently, and the patient died on the 10th of June. The following is the result of the autopsy:

Corpora cavernosa.—On the left side the changes are most manifest in the middle part, which is the seat of a collection of pus.

On the right side the lesions are pretty much the same, but the amount of pus is not so great.

Urethra.—The mucous membrane is injected; in the sub-mucous tissue, near the bulb, there is a collection of pus; the postero-lateral parts of the canal, about four centimetres behind the glans, are dissected up by an abscess; the bulb is infiltrated with pus in the same manner as the corpora cavernosa.

Localization of Brain-Functions (*British Medical Journal*, October 19, 1872).—Meynert, one of the ablest of the modern students of the anatomy of the nerve-centres, has sought, by combining phrenological with clinical and pathological observations on the functions of the cortical layer of the cerebral hemispheres, to define to some extent the localization of the different functions in the gray matter of the cortex. He distinguishes five special functional centres. 1. The olfactory lobe or nerve, which, highly developed in animals well gifted with the power of scent, is almost atrophied in man, less highly endowed in this respect. 2. The walls of the fissure of Sylvius. These are in intimate relation with the power of speech, as is found in aphasia, which is the consequence of changes in them. 3. The occipital and temporal lobes. Anatomy shows the relations of these parts with the organs of the senses,—the retina, labyrinth, and olfactory nerve. In cases of blindness and deafness rapidly developed, these lobes are the seat of evident alterations. The experiments of Flourens on the ablation of the cerebral lobes support this theory; for, if but little of the substance be removed, the senses are not much affected; but if the ablation be carried deeper, the sensorial functions immediately cease. 4. The frontal lobes. These lobes are the principal seat of motor excitation, as is shown by their anatomical relations with the corpora striata. Besides, in the forms of psychoses which are accompanied by extensive disorders of the motility (general paralysis) these are the most atrophied of all the parts of the brain. The continued need of movement, the agitation of mania, are equally based upon change in the frontal lobes. 5. The cornu of Ammon. This organ plays an important part in the functions of motility, and almost always presents, in epilepsy, conditions of atrophy or sclerosis.

Hops as an External Application (*Druggists' Circular*).—If possessed of any virtue as an anodyne, and popularly hops have great reputation as such, the effect is best obtained by *steaming* a muslin bag full of them, on the side to be applied to the body, until quite soft and damp,—not wet.

The ordinary method of wringing out in hot water wastes all the strength of the hops, and makes a nasty mess.

Another Anæsthetic (*Journ. of Pharm.;* from *Wittstein's Vierteljr.*, No. 95, 1873).—*Iodal* ($C_4HI_3O_2$), discovered by Aimé more than thirty years ago, which is obtained by acting upon iodine with a mixture of absolute alcohol and concentrated nitric acid, is recommended by Guyot as an excellent anæsthetic, in doses of one to two and a half grammes. It is a colorless oily liquid, resembling chloral in odor; boils at 25° C., and is decomposed by alkalies into iodoform and formic acid.

MISCELLANY.

Anecdote of Hippocrates (*British Medical Journal*).—Dr. Warburton Begbie, in a recent inaugural address before the Royal Medical Society of Edinburgh, after discussing the reasons for and against the belief that Hippocrates was a witness of the great Athenian plague, says,—

"One other circumstance in the life of Hippocrates is mentioned by Soranus,—namely, his refusal to go to the court of Artaxerxes (surnamed Longimanus) when invited to pay a professional visit. This story, as it has reached us, is as follows. Persia happened to be ravaged with the plague. The governors of Asia

Minor wrote to Artaxerxes to inform him of the high reputation of the Coan physician. The king, in replying, desired the governors to make the most liberal offer, in order to induce Hippocrates to visit his vast dominions. The governors forwarded the letter of the king, and, in doing so, promised in his name every reward and honor which he could wish for or at all desire. The physician, however, refused, and returned answer in these striking words, which, to use the language of a modern French writer, ought to be engraved on the memory of all those of his successors who can think and who can feel. 'I have in my own country the food, the clothing, and the habitation I require. As a Greek, it would be unworthy of me to aspire to the riches and grandeur of the Persians, and to serve the foes of my country and of liberty.' This haughty and memorable answer nearly plunged Hippocrates into trouble; but, when demanded by Artaxerxes to deliver him up, in order that punishment for his insolence might overtake him, the inhabitants of Cos dared the great king, and refused to deliver up a fellow-citizen of whom they had so much reason to be proud, and to whom they owed so much. The firmness of the attitude which these patriots assumed, and the unity by which at that time the different Grecian states asserted their common independence, averted in all probability a Persian invasion, which at first appeared to be all but imminent. Now, in regard to this story, just as respects the one already mentioned of the Greek plague, Dr. Ackermann, in his account of Hippocrates in Fabricius, *Bibliotheca Græca*, Dr. Henderson, and other modern scholars, affect to treat it with disbelief; why or wherefore they do not very clearly state. As opposed to this view, we have the opinions of the accomplished Cabanis and of Dr. Adams, who, while readily admitting that the letters in the Hippocratic collection which relate to this story (these are from the first to the tenth inclusive) can scarcely be received as genuine, find no proof that the event upon which they are made to turn is also devoid of truth. It is evident, indeed, that the ingenious and shrewd French author to whom I have alluded attached very considerable credit to the anecdote, for he has quoted it in both of his well-known works, offering the following apology for the repetition: 'I have already cited it in my essay *Sur la Certitude de la Médecine*, but may perhaps be allowed to repeat the quotation at a time when certain writers seem to be using their utmost efforts to stifle all free and generous sentiments.'"

New York Academy of Medicine.—At the stated meeting of the New York Academy of Medicine, Dr. Austin Flint, President, in the chair, held February 6, 1873, Dr. William B. Lewis, late of New York City, was elected a Non-Resident Fellow. Drs. T. Gaillard Thomas, E. R. Peaslee, James Anderson, Jerome C. Smith, and W. M. Chamberlain made remarks concerning the death of Dr. James L. Brown, a Resident Fellow, and a rising gynæcologist, who died February 4, 1873, from pneumonia, after an illness of three days, aged forty-two years. A committee of three, appointed by the chair, consisting of Drs. Thomas, Chamberlain, and Smith, reported appropriate resolutions, which were unanimously adopted.

At the last meeting of the Council of the Academy, Bradford S. Thompson, M.D., of New York City, was elected Statistical Secretary of the New York Academy of Medicine for five years.

"Settling" a Bill.—The following, from a secular paper, seems to us to have a strong touch of nature in it: "In Texas, recently, a doctor rode fifty miles to attend a patient. After he had cured the patient he presented a bill for fifty dollars, and proceeded to complete his preparations for the journey back to the post, thinking no more about the matter. As he was about to mount, the patient's husband put in an appearance, with his trusty rifle in his hand. 'Doctor,' said he, 'I reckon we'd better settle this here matter now;' and, taking him aside, 'You wa'n't agoin' off without a settlement, was you? I don't want to owe no man nothin'. Here is a ten, which I reckon is about the squar' thing. Now, if you ain't satisfied, just get your weepon and come 'round behind the hill thar, so's the old woman won't be riled up, and we'll settle it. I don't want no man to go 'way from my house dissatisfied, 'specially you, Doc.'"

Ventilation and Warming.—In a lecture on ventilation, lately delivered before the Franklin Institute, Mr. L. W. Leeds, after detailing the abominations he encountered in his examination of the ventilating arrangements of the Treasury building at Washington, gives the following practical directions concerning provisions for ventilation and warming in the construction of buildings. First, never have long underground fresh-air ducts. Second, never allow a sewer, soil-pipe, foul-air flue, or smoke-flue, to come near the fresh-air supply-flue, for fear of some connection being made between them by carelessness or accident. Third, never heat a building exclusively by currents of warm air. Fourth, always put the heating-flues on the outside walls instead of on the inside walls. Fifth, endeavor strenuously to avoid the fresh-air chamber becoming a common receptacle for all the rubbish of a filthy cellar.

Association of French Army Surgeons.—The *British Medical Journal* of December 21, 1872, says, "The medical officers of the army of Paris and Versailles have formed a society. It was first instituted as a club to maintain union and a spirit of confraternity among the members of the sanitary service, but has grown into a society, in which professional interests and questions relating to the special position of the military surgeon are made the subjects of written or oral discussions. The name of 'reunion' has been given to it (in place of its former title of club): the meetings are held every Friday. The society has as its organ the *Bulletin Médical Militaire*, which is published as a supplement to the *Bulletin de la Réunion des Officiers*,—

an evidence of good feeling between the combatant and the medical branches of the service."

The *Lancet* of January 25 says that, "true to his loyalty to the medical art, the late Lord Lytton, in a document addressed to his legal representatives, stipulated that after death, or presumed death, his body should lie untouched three days on the bed on which he died; and that thereafter medical men should examine him to ascertain that he was really dead, and, if so, to certify accordingly. The profession will see with satisfaction that his lordship will receive the honor of interment in Westminster Abbey."

Dealing with Lunatics.—The *Lancet* humorously says, "In view of the cruelties recently perpetrated in lunatic-asylums upon helpless inmates, the recommendation of the late Mr. Charles Buxton must to many appear to be a humane one. This gentleman advised that all insane persons 'should be comfortably shot;' and, with a thoughtful concession to the privileges of the clergy, he added, 'I would have it done with the utmost decorum; perhaps by the bishop of the diocese.'"

Nassau.—This place, on the island of New Providence, offers great inducements to invalids in search of a mild and equable climate; while we are informed that the hotel is an excellent one. Dr. S. Conant Foster, formerly a well-known and highly-esteemed physician in New York City, himself needing the benefits of a southern climate, removed to Nassau a few months since, with the view of engaging in practice there.

Professional Risks.—It was stated in the memoir of M. Guersant, read before the Surgical Society of Paris, that that eminent surgeon contracted syphilis through a wound in his finger received while operating upon a patient affected with that disease, and that his death was the ultimate result of the constitutional infection so produced.

The fatal termination of the illness of Mr. Baker Brown, of London, is announced.

The late eminent Dr. Louis, of Paris, left a legacy to the Medical Association of the Seine, which will add over three hundred dollars a year to the income of that body. It is strange, certainly, that bequests of this kind are so rare, since they would in many instances be greatly to the advancement of science.

Curious Decision.—We see by the daily papers that the Second Comptroller at Washington decides that a soldier discharged for varicocele, resulting from an injury, is not entitled to the one hundred dollars bounty under the act of March 3, 1863. He also decides that varicocele is not an injury.

Commencement.—The Seventeenth Annual Commencement of the Pennsylvania College of Dental Surgery is to be held at the Academy of Music on Saturday evening, March 1, at eight o'clock. The address to the graduates will be given by Dr. Mears, Professor of Anatomy and Surgery.

It is proposed to revive the *Charleston Medical Journal and Review*, as a quarterly of eighty octavo pages. We presume Dr. F. Peyre Porcher, whose name is signed to the prospectus, will be the editor. A list of well-known and efficient collaborators is given as pledged to his support.

Dr. Isaac S. Mulford, long a practising physician and a man of much influence in Camden, N.J., died February 17, aged 73.

Mortality of Philadelphia.—The interments reported at the Health Office for the week ending February 22, 1873, were 303; 163 adults, and 140 minors. 10 were of bodies brought from the country; making the mortality of the city 293. Among the causes of death were:

Consumption of the Lungs	58
Other Diseases of the Respiratory Organs	55
Diseases of the Circulatory Apparatus	13
Diseases of the Brain and Nervous System	52
Diseases of the Digestive Apparatus	14
Zymotic Diseases (2 from Smallpox)	22
Typhoid Fever	3
Casualties	9
Cancer	5
Intemperance	2
Debility (including "Inanition" and "Marasmus")	23
Still-born	16
Old Age	17

(The interments reported for the week ending February 24, 1872, were 484.)

The meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER.		BAROMETER.
	Max.	Min.	(2 P.M.)
Feb. 16	37.0°	31.0°	29.99 in. (Snow and Rain.)
" 17	41.5	35.0	30.15 in.
" 18	47.0	31.0	30.38 in.
" 19	43.5	35.0	30.13 in.
" 20	41.0	33.0	30.29 in.
" 21	39.0	31.0	30.50 in. (Heavy Rain.)
" 22	30.0	20.0	29.97 in.

Death of Dr. Hugh L. Hodge.—As we go to press (Feb. 26), we learn of the sudden death of this venerable member of the Philadelphia profession, which occurred this morning. None of the particulars are as yet known to us.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 18, 1873, TO FEBRUARY 24, 1873, INCLUSIVE.

Vollum, E. P., Surgeon.—Granted leave of absence for thirty days, in lieu of twenty days' leave granted by S. O. 113, of 1872, from these headquarters, of which he did not avail himself. S. O. 25, Department of the Platte, February 15, 1873.

Bill, J. H., Surgeon.—Leave of absence extended thirty days. S. O. 30, War Department, A. G. O., February 8, 1873.

SATURDAY, MARCH 8, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

(Continued from page 323.)

LECTURE IV.

ŒDEMA OF THE LARYNX.

UNDER certain circumstances, a serous, sero-sanguineous, or sero-purulent infiltration takes place with more or less rapidity in the sub-mucous connective tissue of the upper portions of the larynx, and chiefly upon their inner surface; the serous infiltration taking place in cases that run their course with great rapidity; and the sero-purulent, or, in some instances, purulent infiltration occurring in cases in which the action is slower and less violent. At other times a fibrinous exudation takes place, and sometimes an hemorrhagic exudation, into the same tissues. The mechanical result of this condition is, first, to impede respiration, and subsequently to obstruct it; and if the tumefaction does not soon subside spontaneously, which rarely happens, or is not promptly relieved by surgical interference, the patient perishes in a period varying from a few hours to a few days.

Although the disease is prominently located in the sub-mucous connective tissue, it has been found, not infrequently, that the mucous membrane itself has also been the subject of inflammation.

In addition to the mechanical impediment to breathing presented by the infiltration into the tissues, there is reason to believe that there exists, sometimes, a condition of spasm, and sometimes a condition of paralysis of the muscles controlling the opening and closure of the glottis, inasmuch as it has been found in the post-mortem examinations of some fatal cases that the amount of tumefaction was insufficient to account for the whole of the obstruction to respiration. Prof. Stromeyer* has called attention to the circumstance that this observation has not yet had a very great influence in a therapeutic point of view, at least in so much as it refers to the employment of direct remedies against spasm and paralysis.

Laryngoscopic observations of cases of œdema of the larynx have shown that the encroachment upon the normal breathing-aperture is sometimes much less than would be supposed before an inspection of this kind. Although the element of spasm or of paralysis may be in some instances regarded as portion of the direct pathological nature of the affection, there is reason to believe that the extreme nervousness induced by the dreadful fear of a fatal result which attends many cases of impeded respiration, whatever their cause, has much to do with these phenomena of spasm and paralysis.

The most frequent seat of œdema of the larynx is in the ary-epiglottidean folds, both of which are usually involved. Sometimes an effusion takes place into the structures of the epiglottis at the same time; sometimes it is limited to the epiglottis. Occasionally it implicates the vocal cords, converting them into thick obstructing pads, but the infiltration under these circumstances lies in the tissue of the thyro-arytænoid muscle itself, rather than beneath the mucous covering of the vocal cord. To this class of cases alone should be applied the term œdema of the glottis: a term unfortunately too often employed to denote any other œdema of the laryngeal structures also. Sometimes the œdema involves only the tissues immediately beneath the vocal cords, and under such circumstances the condition is designated as sub-glottic œdema of the larynx; a form of this affection to which Dr. Gibb† first distinctly directed attention.

Until the present century the pathology of œdema of the larynx was misunderstood. Its symptoms were usually regarded as denotive of croup in the adult; for although the affection has been known to attack the infant at the breast, and, on the other hand, to make its appearance in extreme old age, it is usually encountered in early and middle adult life. In 1808, Dr. Bayle read his famous paper on œdematous laryngeal angina to the Society of the Parisian School of Medicine; previous to which time, however, Morgagni, in his letter on serous apoplexy, and afterwards Bichat, had described the post-mortem appearances of infiltration of the ary-epiglottidean folds, which had not been detected before death; and at a still earlier period symptoms of a disease which must have been the same thing had been recorded without any evidence of a knowledge of the peculiar lesion which had given rise to them.

Œdema of the larynx sometimes occurs in the course of ordinary acute laryngitis, and constitutes the chief source of immediate danger in that complaint. It is also often present in the traumatic laryngitis following the accidental deglutition of hot fluids or caustic solutions, but it is not produced when they are voluntarily swallowed with suicidal intent.

It is also sometimes met with in the course of pharyngitis, whatever may have been its origin; occasionally, too, in the stridulous laryngitis of children.

It may also make its appearance suddenly during the course of other maladies, and is not confined to such as are ordinarily accompanied by affections of the throat. It is most apt to occur in the declining stages of disease, in the stage of convalescence, or defervescence rather, probably from want of due care as to protection from exposure to currents of air. Thus, it has been encountered in scarla-

* Verletzungen und chirurgische Krankheiten der Halsgegend, Freiburg, 1865, p. 348.

† On Diseases of the Throat and Windpipe, London, 1864, p. 211.

tina, measles, smallpox, typhus and typhoid fevers, erysipelas, farcy, Bright's disease, croup, whooping-cough, pneumonia, and in diseases of other organs productive of anasarca. Ryland* relates a case developed during the progress of measles in a child aged two years and nine months. On the lingual surface of the epiglottis there were found, after death, two deep ulcers, one the size of a split pea; and other ulcers forming a chain which almost surrounded the pharyngo-laryngeal surface of the superior aperture of the larynx. The lips of the glottis were reddened, and so much infiltrated that the ventricles of the larynx were almost obliterated; and the sides of the cavity above the vocal cords were closely approximated to each other. There was no trace of inflammatory action below the rima.

Dr. Reginald E. Thompson† describes a case of irregular ague, with granular kidneys, in which death took place by œdema of the glottis.

Œdema of the larynx is sometimes produced in the course of chronic laryngitis of tuberculous and syphilitic origin; in pharyngitis accompanying malignant disease of the tongue, pharynx, and œsophagus, whether directly implicating the larynx or not; in tumors of the cervical region; in aneurism of the arch of the aorta; and in cases of wounds and other mechanical injuries of the throat and parts adjacent; in cases of abscess and of ulceration of the larynx, whatever their origin; and in cases of the retention of a foreign body in the air-passages. It has also been known to occur from the use of mercury and of iodide of potassium: of the latter Nélaton‡ has related a case in which a female patient became affected with œdema of the glottis while using iodide of potassium; and Prof. Stillé§ mentions a similar and fatal case recorded by Dr. Lanné, in which the amount of the drug taken had been in all but seven and a half grains.

When idiopathic, it is more frequent in men than in women, and in free-livers than in persons of more temperate habits. Although occurring in persons in good general health, it is more apt to make its appearance in those broken-down in constitution or recently convalescent from acute disease; and in many instances there would appear to be some peculiar predisposition towards its production, the nature of which is not understood; for there are instances on record of more than one attack in the same individual.

The approach of œdema of the larynx is occasionally very insidious. Dr. Porter‖ mentions two instances within his own recollection, of young men who had retired to bed at night without complaining, and who were found dead from this affection on the next morning.

When accompanying other diseases, or following them, the occurrence of œdema laryngis may be preceded by the usual prodromata of inflammatory fever; but, as a rule, in this affection we find that its symptoms are marked, and in most cases come on more or less suddenly, and increase in severity with great rapidity. There is usually some tenderness, which only in some cases amounts to actual pain; dryness and heat, with a feeling of constriction in the throat as from the presence of some foreign body there; difficulty of inspiration, often accompanied by a harsh whistling or stridulous sound, and increasing, as the disease progresses, to all the phenomena of impending suffocation; cough to a greater or less degree, which is ineffective because the impediment to respiration, or to patency of the entrance to the respiratory organs, is of a permanent character, and not due to accumulation of matters that can be expectorated; feebleness, hoarseness, or extinction of voice; more or less dysphagia, which at times amounts to complete inability to swallow. The patient soon becomes restless, then anxious lest he suffocate; perhaps he tries to sleep, and may actually slumber for a few moments, but he wakes up after a very short interval, again a victim to his wretched sensations of choking. The face is flushed, the eyes prominent; the respiration hurried, and sometimes spasmodic; the pulse small, quick, and very much accelerated.

Simple inspection of the throat usually reveals more or less inflammation of the structures within sight, and sometimes infiltration of the palate, uvula, tonsils, and occasionally even of the pharynx; but very often no evidence of the disease is apparent in these parts. The infiltration of these parts is most apt to occur in œdema the result of acute inflammation.

The laryngoscopic inspection, where possible,—and it usually can be made,—reveals the nature of the lesion at once. Exploration with the finger is almost always feasible, and permits the detection of the swollen structures, as far as regards the implication of the epiglottis and ary-epiglottic folds. When the epiglottis is involved, it can very often be recognized on pressing down the tongue, appearing usually as a cyst-like eminence projecting above the base of that organ, varying in size from that of a peanut, which it often resembles in configuration, to that of a walnut. Occasionally the swollen ary-epiglottic folds can be brought into sight by inducing an effort of retching, which raises the entire larynx; but when the epiglottis is swollen they are less readily revealed. Sometimes the lingual surface of the epiglottis is not involved; and in such a case a cursory exploration of the structures might fail to determine the diagnosis.

‖ Observations on the Surgical Pathology of the Larynx and Trachea, p. 82.

ances of œdema of the larynx (Fig. 7) are very characteristic. A pale reddish, or sometimes yellowish, translucent swelling, in general appearance not unlike an œdematous prepuce or eyelid, is found occupying the ary-epiglottic folds, usually both of them, though not often in equal extent, and sometimes existing on one side only. These swellings project towards each other, and narrow the laryngeal entrance into a mere slit, which becomes smaller during inspiration, from the downward pressure of the air upon the swellings slightly pressing them together; while during the passage of the expiratory current they are more or less widely separated, and sometimes permit a view of the parts below. Usually all distinct appearance of the so-called false vocal cord is obliterated, the entire mass, ary-epiglottic fold and ventricular band, presenting as one structure. The parts do not exhibit a very vascular aspect, and are sometimes more or less covered with mucus. When the epiglottis is involved, it seems like a huge sac distended with a limpid fluid overhanging the laryngeal entrance, and often hindering a view into the interior of the larynx (Fig. 8). The laryngeal face is but rarely implicated, but the lingual surface and crest are almost always affected. When the disease does not occupy the upper portions of the larynx, the lower portions are seen to project laterally in œdematous protrusion.

Œdema of the Epiglottis.

(To be continued.)

ORIGINAL COMMUNICATIONS.

SOME REMARKS ON BOILS: THEIR PROBABLE CAUSE, AND TREATMENT.

BY JAMES D. McGAUGHEY, M.D.,
Wallingford, Conn.

THERE is a class of individuals—great sufferers—who go from one physician to another, seeking relief, and generally getting turned away with the unsatisfactory consolation that time and patience will effect a cure. The class referred to above is composed of what may be termed "boil sufferers;" and when a crop of those furunculous pests exists on the neck, the sufferer's head is held in a stiff, uncomfortable position, which, with the agonizing pain that accompanies it, renders him an object of charitable sympathy and pity. He seeks in vain for ease, but is compelled to "grin and bear it," or, with Job-like submissiveness and patience, to yield himself up to a process of plasters and poultices until the boils are "drawn (?) to a head." And, after his enemies retire from the field, sad experience teaches him that they, perhaps, will return again and again to the attack, unless the physician prevents.

Dr. Jackson, in his "Letters to a Young Physician," has taken the trouble to write one (Letter No. XVI.) on boils; he appears to express more sympathy for "boil sufferers" than most writers, and says, rather facetiously, "Boils are among the troubles for which your friends will laugh at you rather than sympathize with you; and it is best to laugh too, if you can. But a boil is a *sore* [the doctor uses the right word] trouble; proverbially so." Boils may be Darwinian enough to have a law of "natural selection," as to time and place; but physicians are ignorant of it. For some inexplicable reason, they generally select the back or nape of the neck,—at least such has been my experience; and the next place in frequency has been the face; they also come on other portions of the body, except, Dr. Gross says, "the palm of the hand or sole of the foot."

The boil is a common sequel of eruptive fevers, as every physician knows, and sometimes several congregate, forming anthrax or carbuncle. The cause is obscure,—perhaps would not be so obscure or unknown if men of science having ample opportunity would pay more attention to its discovery, and their zeal for relieving such every-day human pain was equal to their desire for scientific *éclat* gained by research in more intricate and less common fields. Watch a man suffering acutely from furunculus as he goes to his family physician expecting to be relieved and cured. He inquires the cause of his boils, and why he is troubled with such continuous and successive crops. The doctor explains the cause or causes on "general principles,"—that hackneyed set term, which excuses and hides so much ignorance of minute and subordinate causes. The digestive organs are "out of order;" too much rich food,—gravy, butter, etc.,—although the man of boils may be as thin as a ghost; the poor "secretions" are all wrong, the liver "torpid," the blood "too poor," or "too thick," and many other common and *supposed* derangements are mentioned. In answer to an appeal for a cure, our Hippocratic disciple advises low diet, bowels open, poultices, and *patience;* and through a philanthropic feeling welling up in his heart for his suffering patient, and to comfort him before departure, he winds up his speech with the glowing epilogue, "Every boil is worth five dollars, you know." Patient departs "a sadder but a wiser (?) man," and thinks he would part with the whole crop for a "song," and be entirely satisfied with the trade. He, by his suffering and pain, is driven from doctor to doctor, seeking ease and finding none, until, disgusted with poultices, good advice, and patience prescriptions with no relief, he commences taking Jayne's Alterative, or some other analogous preparation highly advertised; the furuncles run their course, get well of themselves, and the patent medicine, having been used at the date of recovery, gets the credit of the cure.

Now, I enter a protest against this treatment generally shown by physicians towards "boil sufferers." What a comforting thought it must be to the

scientific physician, that the boil, the vulgar boil, is an "opprobrium medicorum," while he swells with toad-like pride over his success in discovering and isolating, by indefatigable research, some unknown cell many hundred times less than an inch in diameter, and beautifully coloring and mounting it,—a scientific *success*, to be looked at by few appreciative ones,—"only this and nothing more"! I thought a remark I once heard was quite apropos. A fellow pointed to a celebrated M.D. passing by, and said, "There goes Dr. S.: he can cut your leg off in fifteen minutes, but, d—n him, he couldn't cure my boils." It is the noble office of the medical art to relieve suffering not only in bedridden patients, but where acute pain accompanies man in his daily walk and in his daily business. Because a painful disease is common and does not directly endanger life, is no reason why its cause should not be sought for and checked or obliterated. The only experiments I have ever seen reported regarding the pathogeny of furunculus were by Dr. H. G. Landis, of Ohio, published in this journal. More properly speaking, his experiments did not relate so much to the pathogeny of boils as to the phenomenon of *increase* and *decrease* of leucocytes *before* and *during* the suppuration of his own furunculous sores, establishing the "*identity of leucocytes and pus-corpuscles.*" But his experiments have been suggestive of the cause of furunculus; and if he noticed an increase of the leucocytes in the economy far above their normal amount, and then their *synchronous decrease* with the *formation* of *boils*, it follows naturally that we should suppose the excess of leucocytes to be *eliminated* through the agency of the furunculus. Therefore, we might say, boils are local outlets to a system *temporarily* surcharged with a too great relative proportion of white corpuscles. I say *temporarily*, to answer the question why patients suffering with true leucocythæmia are not invariably covered with boils. For there is not a doubt but that the white cells are very often temporarily out of proportion, relatively to the red globules, from many causes; but this constitutes quite a different condition from *true leucocythæmia*, whose pathogeny is obscure, with involvement of the spleen and lymphatics, and where the proportion of white to red globules is as one to twenty. It does not take a greater relative abundance of white corpuscles in the blood to produce permanent leucocythæmic disease; for look at the system after acute or long exhausting disorders, and it will generally be found leucocythæmic,—perhaps indicating some debility in the organs which generate the corpuscle elements of the blood,—and *such systems very often suffer from severe and successive crops of furunculi;* and if microscopic observation were made in these cases I think we should find the leucocytes disappear as the boils suppurate, and the normal relative proportion between the red and white globules be established. Well, then, if white corpuscles in too great abundance are the cause of furunculus, why are not all cases temporarily affected with leucocythæmia troubled with *eliminative* boils? We might answer, all noxious matters in the economy are not invariably eliminated through the same channels: temperament, season, idiosyncrasy, and a thousand peculiar and modifying tendencies beyond the ken of man and microscopes, work results out in their own legitimate way, and express themselves in phenomena the natural solutions of their own inherent laws; so that, just as circumstances relating to the eliminative organs may be, the superabundant leucocytes are eliminated through the agency of furunculus, kidneys, or the other eliminative avenues of the system. It is hardly supposable that superabundant leucocytes are *eliminated only by changing into pus-corpuscles.* Therefore, leaving out the question, why the leucocytes are superabundant, it is not illogical to conclude that the *temporary leucocythæmic* condition of the economy is the cause of furunculus. But even granting the cause of boils to be known, so far as my knowledge extends, I know of no drug that has the power of reducing the redundant white corpuscles, or has the power to take away that peculiar condition of the system which seems to favor the leucocythæmic tendency. By some physicians the sulphate of quinine has been used empirically, for a number of years, with considerable success in the majority of cases, to prevent the return of successive crops of furunculi. Some have given it as a mere tonic; but Dr. Jackson gave it with quite a different view, because it seemed to him that quinine "operated by taking away or overcoming the susceptibility to the disease." Perhaps this view is an approximation to the true one; the quinine overcomes or takes away that susceptibility of the system, produced by some cause, miasmatic or otherwise, by which a temporary leucocythæmic condition of the circulation is brought about. Perhaps quinine has some direct controlling power over the redundant white corpuscles, or over the cause that produces them. It appears to me as if some experiments relative to this point might disclose something useful as well as interesting. I believe, from my own experience, that quinine given after the time has passed for aborting the pimples by an incision, will shorten the course and circumscribe the limits of furunculus. I remember a very marked case in which boils appeared just inside the external meatus of the ear every winter, at pretty much the same time. Arsenic was prescribed on the second recurrence with very good effect; but on the third recurrence, even after the boil had made considerable advance, quinine checked its growth, and it disappeared without suppurating, and up to this time there has been no recurrence. I know quinine has a remarkable control over superficial inflammations; whenever I am attacked with common sore throat, even though it has existed for twenty-four hours, quinine liberally taken until the head feels it, continued thus for twenty-four or thirty-six hours, will remove all soreness: at least it has not failed me in five several times. I think the best plan to follow in giving quinine is—considering the aborting period to have been passed—to commence as soon as possible and make a firm impression on the system with five-grain doses repeated every four hours until the head rings, keeping the impression up moderately by smaller and oft-repeated doses until the boil has

either suppurated or disappeared by resolution. A strict watch should be kept, so that the first pimple may be detected and incised; at the same time five or ten grains of quinine are given daily till all danger is past. No one need think he is going to be successful in circumscribing the trouble if he begins to give quinine just as suppuration is commencing. The great desideratum is to make a thorough impression on the system with the drug, keeping this impression up moderately with smaller and properly regulated doses, *for a considerable length of time*, according to the requirements of each individual case. According to my experience, arsenic—Donovan's solution, preferably—stands next to quinine. In concluding, I hope physicians will give quinine a thorough and judicious trial in furunculi, be they single, multiple, or in successive crops, as I think it is the only remedy that will circumscribe the limits and shorten the duration and prevent successive crops of those pestiferous sores.

TRANSLATIONS.

VON OPPOLZER'S LECTURES ON DISEASES OF THE ŒSOPHAGUS.

Being the latter portion of the first part of the second volume of Oppolzer's Vorlesungen über specielle Pathologie und Therapie, Erlangen, 1872.

Condensed from the German of Dr. Emil Ritter von Stoffella,

BY DR. J. SOLIS COHEN.

V.

RUPTURE AND PERFORATION OF THE ŒSOPHAGUS.

Rupture of the œsophagus is a very infrequent lesion. Apart from traumatic injury, it is observed, as a rule, only in cases of pre-existing disease of the œsophagus; though under certain circumstances it may also occur when the tissues are in a healthy condition. Ulceration, inflammation, mortification, carcinomatous degeneration, and constriction of the œsophagus, predispose to rupture.

The rupture occurs in most instances during violent bodily exertion, or during a severe effort of vomiting; though, as mentioned, usually only when the organ is diseased. Oppolzer saw but one case of rupture of a sound œsophagus. It occurred in a woman who was making violent exertions in ironing, during which the rupture took place, with fatal hemorrhage into the mediastinum. In the case of Admiral Vastenaer, observed and recorded by Boerhaave, the rupture occurred during an effort to vomit directly after a meal. The lower portion of the œsophagus gave way at an ulcerated point, and the contents were discharged into the thoracic cavity.

The *symptoms* of a rupture of the œsophagus are as follows: A severe pain suddenly supervenes in some portion of the œsophagus during vomiting or some movement requiring powerful physical exertion; at the same time there is vomiting of blood; with a sense of great anxiety and dread on the part of the patient, a result of the escape into the mediastinum of blood and air, and sometimes of the contents of the stomach; the extremities become cool; collapse and syncope set in; and death takes place usually in a very short time. All these symptoms are quite vague, inasmuch as they only point, in a general manner, to the existence of some severe malady, without indicating its particular seat or determining its exact nature. Auscultation of the act of deglutition throws more light upon these obscure phenomena. When a patient with a ruptured œsophagus swallows a mouthful of liquid, it can be determined by the deglutition-sound that the bolus descends to a certain point only. This point, according to Hamburger, is the opening of rupture. Not infrequently a slight whistling sound is also heard on swallowing. "This takes place only when the rupture is large enough for the liquid bolus to pass through it. If the opening is too small, there is no communication, and the rupture is latent." Auscultation, however, is only of questionable value, for the patient is usually so far advanced in collapse, by the time of the surgeon's arrival, that it is impossible to auscult the act of deglutition. When auscultation is undertaken, but a small quantity of water should be swallowed at a time, and the experiment should not be repeated often, lest the frequent deglutition enlarge the rupture.

The *diagnosis*, according to Von Oppolzer, can be determined only when a severe pain suddenly occurs in the course of the œsophagus during the act of vomiting, and from that moment ingesta are no longer vomited, but simply blood in greater or less quantity; and when, in addition, earlier manifestations had already pointed to the existence of disease of the œsophagus. The diagnosis would be confirmed, if on auscultation the deglutition-sound should vanish at some particular spot along the course of the œsophagus.

The *prognosis is unfavorable*, the rupture almost always, if not always, terminating fatally.

The *treatment* consists in forbidding the swallowing of food or drink, in the hope of promoting adhesion of the edges of the rupture. Thirst is to be relieved by keeping bits of ice in the mouth, or sucking slices of orange. Ice may be applied externally. Soups, yolk of egg, and other nutritious substances must be administered by injection.

PERFORATION OF THE ŒSOPHAGUS.

Perforation of the œsophagus is distinguished from rupture by the slow and gradual production of the solution of continuity, and its occurrence only in cases where the coats of the œsophagus have been already diseased for a longer or shorter time. The perforation may take place from within outwards, or from without inwards. From within outwards, by the retention of spiculated bodies; by the deglutition of corrosive substances; by ulceration, inflammation, abscess, gangrene, cancerous disease, in so far as these affections penetrate into the substance of the organ: from without inwards, chiefly from peri-œsophageal abscess; from cheesy degeneration and purulent destruction of lymphatic glands near the œsophagus; from aneurisms, caries of the vertebræ, abscess of the trachea or the adjacent lungs, cavities in the lungs, gangrene, cancer of the lung, purulent pleuritic exudation, etc.

The perforation may occupy any part of the œsophagus, but is usually found in its thoracic portion. The opening is either single or multiple; in form either irregular with torn and readily-bleeding edges, or round with sharply-defined edges, similar to those of gastric ulcer. If the perforation has occurred from within outwards, the mucous membrane is torn to a greater extent than the muscular coat; the reverse is the case when the perforation has occurred from without inwards.

A perforation having taken place, the contents of the œsophagus, and air with them, especially on swallowing, escape into the surrounding connective tissue, or into the mediastinum, or into an organ which has previously contracted permanent adhesion to the œsophagus at that point,—as the trachea, primary bronchi, lungs, pleura, and pericardium. As a further result of

this escape of matters from the œsophagus, we may have inflammation, suppuration, and sloughing of the tissues into which they have been discharged. In this connection we also have erosion of large or small vessels, and, as a consequence, hemorrhage, which may often be fatal.

The communication of the œsophageal perforation with the adjacent organs may be direct, or by means of a longer or shorter, straight or tortuous fistula.

The *symptoms* of perforation of the œsophagus are not infrequently involved in obscurity, owing either to the cause of the perforation, or sometimes to its locality. In general, symptoms of disease have preceded it, pointing to inflammation, ulceration, stenosis, or compression of the œsophagus. Only occasionally does it occur that an ulcer of the œsophagus perforates that organ without having given rise to any previous symptoms; as in the cases of Copland and Von Bamberger.

The moment at which the perforation itself is made is usually indicated to the patient by a more or less severe pain, or a sensation as if "something had given way" inside; by vomiting of pus or blood, or so-called tuberculous slough; by a feeling of anxiety, oppression, or a sense of suffocation. Sometimes the moment of perforation is altogether unnoticed. Dysphagia suddenly ceases upon the occurrence of perforation, so as to give fresh encouragement to the patient, and also to the physician if he has had no experience in these cases. The œsophageal sound, the passage of which was attended before with great difficulties, now passes readily as deep as you will; especially when the pleura or pericardium has been perforated (Hamburger). The auscultatory phenomena are similar to those already described in connection with rupture of the œsophagus.

The symptoms following perforation vary with the seat of lesion, and the organ with which the œsophagus is in communication. If the perforation is in the cervical portion of the œsophagus, a tumor is formed, with subcutaneous œdema which not infrequently extends beyond the shoulder. The tumor feels puffy, as a rule, and, after a longer or shorter time, usually ulcerates, under which circumstance a fistula is formed, out of which, as soon as it has broken through externally, the food that is swallowed comes to the surface.

If a communication has been made between the œsophagus and the posterior mediastinum, there is severe pain in the depth of the chest; dyspnœa; more or less manifestation of fever; subcutaneous emphysema, spreading from the upper outlet of the thorax over the neck, face, and often over the upper extremities, and the entire trunk.

If the communication is with the pleural cavity, whether the perforation have proceeded from the œsophagus or from the pleura, there are symptoms of pneumothorax, and pleuritis.

If the trachea is penetrated, or the lungs entered, then, on auscultation of the liquid bolus, a metallic gurgling sound is heard at the point of perforation, and severe cough and suffocative paroxysms occur at the moment of deglutition, the liquid being propelled outwards through the mouth and the nose. If the communication be due to abscess of the lung, or a vomica, the symptoms will be a sudden and more or less copious discharge of pus or tuberculous slough. Similar symptoms follow perforation into the œsophagus from purulent pleuritic exudation.

If there is a communication with the pericardium, there will be symptoms of pericarditis for a longer or shorter time, and, in addition, symptoms of pneumo-pericarditis,—accumulation of air and fluid in the pericardium.

If an aneurism ruptures into the œsophagus, there is profuse hæmatemesis, rapidly followed by death.

The *prognosis* depends on the cause of the perforation. Most cases terminate fatally, and, according to Vigla's statistics, at a period varying from four days to six months. Recovery takes place, as a rule, only by the opening of an abscess in the œsophagus, and by its rupture externally.

The *treatment* requires the forbidding of attempts to swallow. Food must be administered by the stomach-tube, a procedure which requires special skill and caution, to avoid engaging the tip of the instrument in the perforation. If the use of the stomach-tube is, for one reason or another, impracticable, we resort to nutrition by means of enemata. For the relief of thirst the same measures are recommended as have been mentioned in connection with rupture of the œsophagus.

The secondary effects of the perforation, as well as its primary cause, require the employment of treatment in accordance with their therapeutic indications.

Mycosis (by Debove: *Le Mouvement Médical*, October 12, 1872).—This very interesting case concerns a man forty-two years of age. It was noted during the life of the patient that he had, while living in Cayenne, contracted intermittent fever, which had, however, disappeared upon his return to France. It was also noted that he had received, in the beginning of the year, a contusion of the shoulder.

In March he observed that his right breast was swollen, and that the left one soon became similarly affected. They increased in size, and the patient was sent to the Hôpital Saint-Louis (service of M. Bazin).

On his admission, tumors were observed in the hairy scalp, and in the parotid regions; the former were of the size of an egg, the latter were as large as the fist. The surface of one of those in the parotid region was ulcerated. On the body the tumors varied from the size of the fist to that of a marble; the hair on the surface over them had fallen out. If the statements of the patient be believed, the tumors when they first appeared resembled maculæ, and a certain number of them had disappeared spontaneously. The sub-maxillary, the cervical, the axillary, and the inguinal glands were enlarged. The glandular enlargement did not bear a direct proportion to the size of the tumors; for the glands of the groin were especially large, and yet in the leg the tumors were few in number and of comparatively small size.

The various internal organs, excepting the spleen, which was slightly enlarged, were in a healthy condition. The blood presented nothing abnormal. M. Bazin stated that the symptoms pointed either to mycosis or to syphilitic manifestations. But, in the absence of the lichenoid eruption which usually accompanies mycosis, M. Bazin decided upon the latter diagnosis, and prescribed the biniodide of mercury, which, however, had soon afterwards to be stopped.

Oppression in breathing occurred. The tonsils were swollen and ulcerated. In August the tumors rapidly disappeared, and the patient's face again presented a natural appearance. But the pulmonary embarrassment persisted; the patient lost all desire for food, and failure of strength became more and more marked. He finally died. Examinations of the blood, made at various times, never revealed an increase in the proportion of the white corpuscles. At the autopsy, made on the 28th of August, the spleen was found enlarged. The liver and all of the other organs were healthy. The lymphatic glands, congested in some places, had undergone follicular hypertrophy. In a word, the same lesions were present as have been observed by MM. Malassez, Gillot, and Landouzy.

The present case differs in the absence of the lichenoid eruption, and in its course, from those previously reported.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 8, 1873.

EDITORIAL.

CURIOUS INCONSISTENCY.

A RECENT number of the *Wheeling Daily Intelligencer*, handed us by a friend, contains an account of what seems to us a remarkable transaction.

It appears that the Board of Commissioners of Ohio County, in which the city of Wheeling is situated, had advertised for bids, on the part of physicians, for "attendance on the poor, examinations of lunatics, and post-mortem examinations in case of medico-legal investigations, to be awarded to the lowest bidder by the year." At a meeting of the Board held February 3, a communication, justly setting forth the disadvantages of this method of securing public professional services, and signed by eighteen physicians, was presented, and laid on the table. But the very next item in the reported proceedings of the Board was the presentation of three proposals, two of them from gentlemen whose names were appended to the memorial. And one of these bidders, who offered his services for $350, was actually elected to serve at a salary of $500, the latter being the sum allowed by law.

Why the Board advertised for bids, when there was an ordinance fixing the amount of compensation for the duty; why the doctors offered to serve at a lower rate of pay, in the face of their own remonstrance against the very proposal to them so to underbid one another; and why the Board, having sought and received overtures for the undertaking of the work at a low price, should have elected one of the highest bidders to do it at an even higher salary,—all these points are beyond any arithmetic we have as yet been able to bring to bear upon them.

HEALTH OFFICE RETURNS.

THE profession in this city will be glad to know that the Board of Health will hereafter issue, in a creditable form, a weekly return of the deaths and interments reported to them. Besides the general statement of the assigned causes of death, the proportion in each ward, the nativities, the comparative weekly mortality, and the meteorological observations taken at the Signal Office in the Chamber of Commerce, will be presented. This is a matter in which we have hitherto been liable to unfavorable comparison with London, Boston, New York, Baltimore, and other cities.

Our Health Office, although it might by suitable legislation be rendered an agency of far greater usefulness to our rapidly increasing population, has been for some years past in excellent hands. The Board is composed of gentlemen of intelligence and high character, and its officers have shown both judgment and energy in their performance of duty. We think that all our physicians who have come in contact with Mr. Addicks, the Health Officer, or Mr. Chambers, the Registrar, can testify to their uniform courtesy and promptness in dealing with matters brought before them.

We trust that at no distant day the subject of the law concerning the administration of sanitary affairs in this city will come before one of the influential medical societies,—perhaps be made a matter of joint action,—and that the result will be an increase of the powers now vested in the Board of Health, so that it can more efficiently carry out the objects of its existence.

A SINGULAR AFFAIR.

ALLUSION has several times been made in our columns to the subject of apparent death, and the fear of premature interment which is so generally entertained. We do not believe that there is the slightest ground for this fear, if ordinary precaution is observed; and we note the following case, from the New York correspondence of the *Public Ledger*, as an instance of the neglect by which such frightful accidents may be brought about:

"A colored servant-girl, named Carrie Johnson, to all outward appearances died on Friday morning last

February 21, 1873, at No. 33 Morton Street, and later in the day a permit was granted to convey the body to the Morgue. The driver of the dead-cart, however, discovering that portions of the body were still warm, sent for a doctor, who at once began efforts for resuscitation, and these proved successful, the girl returning to conciousness soon afterwards. She is now, apparently, as well as ever."

It does not appear whether or not the girl had any medical attendance, or what was the supposed cause of her death; nor is it stated that any physician's certificate was required in order that the permit should be issued for removing the body to the Morgue. It must, however, be considered very strange that the first person to entertain any suspicion of a mistake was the driver of the cart. If no professional opinion was obtained as to the actual death of the girl, there was gross neglect on the part of her "friends;" if any physician did certify to this, he must be held to have failed either in the care or the skill which was demanded in the premises. The matter seems to us, on public grounds, to call for investigation.

LEADING ARTICLES.

RECENT IOWA LEGISLATION CONCERNING INSANE HOSPITALS.

THE gentlemen of our profession who have devoted their lives and labors to the treatment of insanity have recently experienced an additional, if not wholly novel, sensation. The sanguine may have imagined that their cup of obloquy and reproach was already filled. Charges of corruption had long become familiar as household words. Indeed, the public seemed to fancy that they should bear maligning as sweetly as the proverbial eel bears skinning, and have as little right to complain. If we have fished in the mud for an illustration, it is not without fitness, since the foulest of mud is thrown at decent men by people who have only the muddiest notions of the subject on which they dogmatize. Concerning typhoid, or cholera, or pneumonia, the average layman does not, as a rule, assume to know better than his physician. He seldom proclaims in the streets that his phthisical neighbor is the victim of conspiracy, between relations and the doctor, aiming at his destruction. He does not commonly accuse a reputable physician of seeking with fiendish ingenuity to protract the acute endocarditis of a patient into permanent invalidism. But let another neighbor be taken to an insane hospital,—and it shall be marvellous to behold how our goodman rises to the occasion. His speech is oracular and dogmatic. He is hampered by no doubts of his ability to judge and determine the matter, nor of his call so to do. No false modesty, no absurd scruples as to meddling, seal his lips or stay his hands. No perception of delicate distinctions, no respect for the wisdom of experts, no conscious ignorance of facts or principles, troubles the supreme complacency with which he utters his belief. When his opinion conflicts with that of physicians and friends, the boldness with which he supports it amounts almost to moral grandeur. Fraud, conspiracy, bribery, hatred, and cupidity, are the charges hurled at all who differ. The friends of the victim may have led decent lives and enjoyed good repute. They may never have been even suspected of robbery, murder, or rape. They may even have been deemed kind, amiable, and upright in their families and in society. The physicians, too, may have been credited with some share of respect and esteem as honorable gentlemen. But what is all this to Mr. Smith who believes Mr. Brown to be sane? Either his pride of opinion, or the fair fame of other men, must be sacrificed: and how can a free and enlightened American citizen hesitate for an instant?

Sad as this popular prejudice and suspicion are; hard as it is for medical men to bear outrageous calumny and reproach; harmful as have been the results, in depriving the insane of early hospital treatment, and in causing distrust and disregard of the physician's advice,—it is only within a year or two, and in one State, that a legislature has been so misguided as to pass a law whereby the management of its own asylum is to be shaped by the current ignorance, prejudice, and fanaticism of the day. By this act a blow is struck at the whole modern system of caring for the insane,—a system which is the result of nearly a century of philanthropic labor and study, marked by steady progress in all means of cure and comfort. For, inasmuch as no man with a proper self-respect could consent long to hold a superintendency hampered by conditions so degrading and mischievous, such positions would inevitably fall only to the inefficient or the incompetent.

The law in question is entitled, with exquisite unconscious irony, "An Act to protect the Insane." It was passed in April, 1872, by the General Assembly of Iowa.

Section I. orders the appointment by the Governor of a Visiting Committee to visit the Insane Asylum "at their discretion,"—a later section

ordering the visitation to be at least monthly. Power is given "to send for persons or papers and examine witnesses on oath, to ascertain whether any of the inmates are improperly detained in the hospital, or unjustly placed there, and whether the inmates are humanely and kindly treated, with full power to correct any abuse found to exist." It is added that any injury or abuse proved shall be treated precisely as if committed outside the hospital. "The testimony of patients shall be taken and considered for what it is worth." No asylum employé is allowed on the jury trying such cases. The Committee is vested with power to discharge any officer or attendant found guilty of abuse. An annual report to the Governor is required.

Section II. orders the keeping posted in every ward of the asylum the names and addresses of the Committee. Every inmate must be allowed to write when and to whom he or she pleases. The superintendent is required to forward all letters, either to the party addressed, or to the Committee "for inspection before [being] forwarded." "Any member of this Committee who shall neglect to heed the calls of the patient to him for protection, when proved to have been needed, . . . shall be discharged by the Governor."

So far as the ends sought in these sections are good, they were already provided for. Every hospital for the insane in this country, either State or corporate, has its regular board of trustees, managers, or directors. These are, almost without exception, appointed on the ground of high character and social position. In many cases, some of them, if not all, are the picked men of the community, universally considered as above suspicion. As if ashamed to require by law, of such men, duties which their own consciences would enforce, this Legislature thrust upon and over them such a committee as is here provided for.

No provision is made for determining the questions sure to arise under the second section. In fact, it may serve as a tolerably fair example of the *reductio ad absurdum*.

Section III. obliges the superintendent to provide stationery, etc., once a week to all who ask it. A proviso follows, which, in somewhat dubious and ungrammatical phrase, empowers the Committee to suspend or take away these epistolary privileges. How is this reconcilable with the requirements of the preceding section?

Section IV. requires the superintendent to forward the weekly letter unexamined and duly stamped.

Section V. orders the delivery to patients—and also unexamined—of all letters directed to them: *provided*, these come through the Committee.

Section VI. orders coroner's inquest in all cases of "sudden and mysterious death." Whose judgment is to decide as to these characters in each case of death, is not stated,—an omission which becomes important in connection with the pains and penalties next prescribed.

Section VII. ordains that failure to comply with, or wilful and knowing violation of, "any of the provisions of this Act, shall upon conviction thereof be punished" by imprisonment under three years or fine under $1000, or both, at discretion of the court, "*and by ineligibility for this office in future.*" Testimony, sane and insane, to be "taken and considered for what it is worth."

Section IX. allows the members of the Committee five dollars a day for time spent in visiting the hospital, with mileage as given to members of the legislature. We can fancy the pleasurable alacrity with which the "disbursing officer of such asylum shall pay the per diem and mileage" upon certificate of each member of the miles and days consumed in his philanthropic mission:

> "What! pay the dentist, when he leaves
> A fracture in your jaw?"

The last section orders that "This Act, being deemed of immediate importance, shall take effect from and after its publication" in certain designated papers. By such publication this extraordinary fruit of prejudice and folly became the law of Iowa in forty-eight hours after its approval by the Governor.

It may be not uninteresting to give, in a subsequent article, some account of the means and influences which procured this remarkable legislation, and to set forth its tendencies and its practical working.

PHOSPHORUS.—The *Druggists' Circular* says: Dr. Radcliffe has recommended the following formula for gelatinized phosphorus pills:

"Phosphorus	6 grains.
Suet	600 "

"Melt the suet in a stoppered bottle capable of holding twice the quantity indicated; put in the phosphorus, and when liquid agitate the mixture until it becomes solid; roll into three-grain pills and cover with gelatin. Each pill will contain nearly $\frac{1}{33}$d of a grain of phosphorus."

The following formula by Soubeiran of a "potion phosphoré" is given by Dorvault as the best method of administering phosphorus internally:

"Phosphorated oil	8 parts.
Gum arabic	8 "
Peppermint water . . .	100 "
Syrup	60 "

Make an emulsion."

CORRESPONDENCE.

LONDON LETTER.

[*From Our Own Correspondent.*]

The Case of the Emperor Napoleon III.—The Scientific Question involved—The Ethical Question—Private History of his Illness—Consultations—The Operation and Post-mortem Examination—Uræmia the Cause of Death—Sir William Gull's Postscript—Opinions of the London Profession—Forthcoming Report—The Societies—Arteriosis in Bright's Disease—New Presidents.

LONDON, February 13, 1873.

THE chief subject of discussion in medical circles in London since the opening of the new year has been the circumstances surrounding the death of the Emperor Napoleon III., and the course pursued by the principal medical attendants. There are two aspects of the question, both interesting to medical men, not in London only, but in all countries. The first is scientific, the second ethical.

The sudden death of the Emperor, the character of the previous reports, and the statement of the post-mortem conditions, raised at once the question whether the case was one in which any operation should have been performed, and, if so, whether the selection of lithotrity in place of lithotomy was judicious. The elements for judgment were briefly these. The Emperor was a man of shattered constitution, past the middle period of life. For some years he had been suffering severely from symptoms correctly diagnosed two years before as those of calculous pyelo-cystitis. You will have seen the very clear and explicit "consultation" drawn up by M. Germain Sée, shortly before the outbreak of the Franco-German war, after an examination of the Emperor by himself, Conneau, Corvisart, Nélaton, and Ricord. It has been published here and in France, and, I dare say, has reached you before this: in case it has not already been laid before your readers, I enclose a copy of it. The medical advisers of the Emperor were, therefore, at this time perfectly aware of the probable existence of stone, but the Emperor himself was extremely averse to entertaining that opinion, and most unwilling to submit to examination, which indeed was at that time a political impossibility. To quote the words of an illustrious personage in describing his position and feelings on the subject, "he was aware that in France, especially in the then state of parties, to be ill and physically incapable of guiding state affairs was more dangerous and a greater offence than to commit any kind of political or moral error."

Moreover, as the pain which he suffered was, as is often the case, chiefly localized in the rectum, the Emperor persisted throughout in believing that his chief trouble was from hemorrhoids. Thus he started for Sedan without defining his physical condition. The subsequent disasters, and the state of political uncertainty into which the affairs of France were thrown after the peace and following upon his release from Wilhelmshöhe, prevented him from adopting more than palliative measures. During the autumn of 1872 he was seen not only by his private attendants, but by Sir James Paget, M. Nélaton, and Sir Henry Thompson. He was suffering from constant pains in the rectum and extreme irritability of the bladder. M. Nélaton did not even think it wise to introduce a sound. It was only on the second visit that Sir Henry Thompson was allowed to sound the Emperor. He then ascertained at once the presence of a large stone, and the urgent necessity for an operation to remove it was so clear as to admit of no question. As to the choice of operation there could be but little doubt. Sir James Paget expressed his entire concurrence in the selection of lithotrity, in a letter which he wrote to a friend in Paris and which was published in the Paris papers. To have cut a patient with such a condition of bladder at that age, and with an amount of kidney-disease which could not be ascertained, would have been an act of the highest surgical rashness. The stone, it was evident, was phosphatic, and hence by its softness lent itself to the operation of crushing. The successive sittings were followed by extreme irritation, violent tenesmus and rectal pain being the most troublesome symptoms. The sittings were in themselves satisfactory, and the stone, as the post-mortem showed, was dexterously handled,—one-half being quite crushed away, while the rest had been left intact, a mode of manipulation which is of course clearly the best, as leaving fewest fragments at a time in the bladder, but by no means easy to compass. The rapidity with which one sitting followed the other has been criticised, but the reason for it was that it seemed necessary, to remove obstructing particles of calculus, and that after each sitting the previous irritation was diminished. In this respect the Emperor's condition was satisfactory on the day before his death. There were, however, signs which afforded reason for uneasiness. Chief of these was a suspicious drowsiness: this was particularly marked on the night before his death. It had created the suspicion of slight uræmic poisoning for some days; but there were other circumstances which suggested a more hopeful view. The urine was of good specific gravity, 1020, and, although the Emperor slept heavily on the night before his death (a slight opiate having been administered to relieve irritation), he did not sleep with the drowsy stupor of an uræmic and poisoned brain: he dreamed distinctly and vividly, and recounted next morning with vivacity the scenes through which he had passed, and the incidents of his nightly vision. Mustard-plasters had been applied to the loins, but these he would not allow to stay on long. The morning of his death, as you know, passed quietly and favorably. He was visited by his medical attendants, and expressed himself as feeling more comfortable than for days past; and a further sitting was to take place at noon. Before going in to their *déjeûner*, Sir Henry Thompson and Mr. Clover, the chloroformist, who had slept in the house, entered the room to pay a short visit, and found, to their surprise and grief, that a sudden change had occurred and that the nurse was about to summon them. The Emperor was comatose and nearly insensible; the pulse imperceptible, and breathing stertorous. The dangerous state of things was immediately seen. Baron Corvisart was

summoned, and the members of the imperial family. In about a quarter of an hour he was dead, never having rallied or regained consciousness. He was not speechless, but in faint muttering delirium.

The post-mortem disclosed, as you are aware, a considerable amount of kidney-disease, the ureters dilated to the size of the aorta, and the tissue of the kidneys atrophied; what was left being, however, tolerably healthy. Of the interpretation of the case and its issue no educated physician or surgeon here entertains now, I think, any doubt. It was distinctly a case, such as we all know, of uræmic poisoning. The bladder was uninjured by the lithotrite; there were no abscesses in its vicinity; the shock of the operations and the communicated irritation to the kidneys had arrested the function of that part which was left of them, and which previously had been carrying on the work of excretion. With so much of disease, a little is enough to disturb the balance. There has been some misapprehension and some reproach by non-medical writers as to the statement in the post-mortem report, that the extent of the kidney-disease could not be ascertained during life. Medical men, however, well know that where the disease of the kidney is atrophic and not primary, but secondary to increased backward hydraulic pressure from an obstructed bladder; and where the urine is loaded with the products of vesical inflammation, the ordinary means of diagnosis are baffled; and, much as it may be regretted, it is indeed true that the amount of kidney-disease cannot be ascertained in such cases.

So much as to the scientific aspects of the case, on which, however, possibly some further light may be thrown when the full details are published, as they presently will be over the signature of Dr. Corvisart, Sir Henry Thompson, and Sir William Gull.

The ethical question raised has been owing to the course pursued by the latter physician in appending to the short post-mortem report officially signed a note of his own, raising a doubt or expressing a separate opinion as to the etiology of the stone. The report seemed to intimate that the bladder-symptoms were probably secondary to the phosphatic calculous formation. The stone, however, was one of very rare structure, almost as rare as is cystic oxide calculus. This had been pointed out by Sir Henry Thompson to his colleagues, and the etiological questions connected with it had been discussed. (It has since been placed in the hands of Prof. Williamson, F.R.S., of University College, for analysis, and we shall have a minute account of it hereafter.)

The post-mortem was performed, in the presence of all the medical men concerned in the case, by Dr. Burdon-Sanderson, F.R.S., selected for his eminence as a pathologist. Sir William Gull was present at the post-mortem, which occupied three hours, but begged to be allowed to leave when his colleagues were about to draw up the report, as he had to proceed from Chiselhurst to London to take the chair that night at the Clinical Society of London, it being the last sitting of his year of presidency. He requested, therefore, that the report when concluded should be forwarded to him in the evening for signature. This was done; and it was on reading the report sent to him, apart from his colleagues, that he added, without consultation with them, the postscript which has been so much criticised. It is generally held that, although unobjectionable in itself, the addendum was open to objection as raising a point of purely etiological interest unnecessarily, at a moment when no such discussion was called for, and in the presence of an uninstructed public, who could only view unfavorably any kind of dissent, on however small a point, and who could not enter into any such discussion, but could only conclude that on some abstruse point Sir William Gull either was or thought himself wiser than his colleagues. Such departures from professional regard for the mutual good understanding and equality of respect which should prevail among medical men are naturally regarded with great jealousy and disfavor; and the higher the position of a medical man the more he is held bound to afford an example of scrupulous delicacy and generous self-abnegation, if necessary, in his dealings with his professional brethren. I do not remember ever to have met with an instance in which professional opinion has been more strongly aroused; and, although the offence is one which is too impalpable to be easily dealt with, and too easily explained as due to inadvertence to be officially noted or condemned, the well-understood and universal opinion of the profession has placed Sir William Gull on a lower pedestal than he occupied before. The public, however, are but little affected by such verdicts; and such is the popularity of this very accomplished physician that he will suffer nothing in his material interests. It still requires an appointment of three weeks' date, commonly, to secure his services, and no peer, bishop, or cabinet-minister can die respectably without his assistance. The profession also, recognizing his many high qualities, will not fail to restore him presently to favor. But it will be long before this slip is forgotten.

Scientifically, in London we are still occupied in discussing Dr. George Johnson's views on "arterio-fibrous degeneration" in Bright's disease, which he declares to be a figment of the microscope, and due to the use of glycerin in mounting the preparations. A committee of the Royal Medical and Chirurgical Society was nominated to examine the preparations and give judgment, but they have for the most part declined to act, on the ground that to obtain a solution would require more time and research than they are able to give to the subject. A new committee will have to be appointed.

Mr. Prescott Hewett has been nominated as President, for this year, of the Clinical Society of London. He is a favorite surgeon of the aristocracy, senior surgeon to St. George's Hospital, and highly educated in surgery and in the arts, but not much given to professional amenities, and his election was rather a tribute to his hospital than to himself. Sir William Jenner, at this moment the most respected and perhaps the ablest practising physician we have, is the new President of the Pathological Society; and the veteran Dr. C. J. B.

Williams—"Alphabet Williams"—is to be the new President of the Royal Medical and Chirurgical Society.

I must reserve further news for my next budget.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held January 22, 1873, at 8 o'clock P.M.,

Vice-President H. H. SMITH in the chair,

Dr. H. H. SMITH, with the view of drawing out the experience of the members present, called attention to the prevalence of pneumonia and erysipelas during the last few weeks. He could not say that it was epidemic; but several cases of pneumonia had been seen by him, and he had heard of others among his friends in the district between Market and Lombard Streets and west of Tenth Street. These cases were attended by marked typhoid symptoms and had terminated fatally in a few days. He had also seen some erysipelas of a typhoid character, one case of which had terminated in extensive sloughing and death.

Dr. HAMILTON said that the desire expressed by the chair to hear the opinions of members present on the subject of the prevailing pneumonia was well timed. The disease, according to the weekly reports of the Board of Health, has been much more than usually fatal. Including, as may properly be done, the deaths from congestion of the lungs with those from pneumonia, we have for three weeks past a total larger than that of the deaths occasioned by phthisis.

This was, to his recollection, an almost unexampled prevalence of disease of the respiratory organs in this city, and deserves the careful scrutiny of the profession to determine the agencies, whether zymotic or otherwise, influential in producing it. He had not had a well-marked case of pneumonia in his own practice, and was, therefore, anxious to learn what had been the experience of other gentlemen, and desired especially to learn to what extent the congestive element had complicated the disease. Many years ago, pneumonia in a low form caused a large mortality, and was then, and has been since, returned as "typhoid pneumonia." May not the present malady be of this type, and, if so, its congestive character be conceded, since an examination of the history of nearly every epidemic of acute disease productive of great and sudden fatality establishes the existence of this element, potential for evil?

In reference to the influenza or catarrhal affection now so widely prevalent, Dr. H. had observed an unusually large number of protracted and obstinate attacks; he believed, as a rule, that inflammation of the nasal and respiratory passages was more than usually frequent, in comparison with that of the adjacent organs.

In regard to erysipelas, he had seen but a few mild cases; and if the disease prevailed so extensively as some supposed, it must be of a favorable character, as is negatively but conclusively shown by the weekly returns of the Board of Health.

Dr. R. BURNS had seen, in the northern portion of the city, a number of cases approaching pneumonia, characterized by a congestive condition. The respiratory murmur was subdued,—no crepitus perceptible; pulse depressed; the fauces so tender as to produce difficult deglutition; eyes suffused with coryza; aching of the limbs and lumbar region, with much uneasiness, headache, loss of appetite, and chilliness, although the skin felt feverish. In these cases, although the fauces were much inflamed, and there was very often tenderness and swelling of the cervical lymphatic glands, yet the tonsillitis did not proceed to suppuration. He considered these cases as influenza, and thus far had observed no true pneumonia, nor had he seen any cases of death from this disease.

The treatment he had used consisted in hot mustard pediluvia, and a diaphoretic draught, to be followed in an hour with hot lemonade. After free diaphoresis there was generally amelioration of all the symptoms in a short time, when ten or fifteen grains of quiniæ sulph. were given, and convalescence ensued. He had not met with any erysipelas.

Dr. ASH remarked that he had been attending a larger number of cases of tonsillitis than usual at this season of the year, also some erysipelas. With the present improved treatment of this disease, however, the mortality has been greatly reduced.

Dr. DEAL had seen no erysipelas in Kensington district, but in the central portion of the city he had seen much more than usual. He had seen a good deal of influenza in Kensington.

He had seen no tendency to traumatic erysipelas in the small hospital with which he was connected, although there had been quite a number of operations.

Dr. WITTIG had seen, in a boy eleven years of age, a case of erysipelas, ushered in by headache and its peculiar fever. It commenced on the nose, and extended to the right cheek and orbit, bullæ being formed on the surface. His grandfather had died a year ago from the same disease, treated by stimulants and tonics according to the new method. Dr. W.'s treatment was to give simply the neutral salts, together with the neutral mixture, and purgatives, and to cover the affected parts with aromatic herbs.

He had also had two cases of pneumonia affecting the lower part of the lung. Nitre, tartar emetic, and muriate of ammonia internally, together with an occasional dose of acetate of lead and opium; externally, unguent. iodinii, constituted the whole treatment.

He remarked that in cases of rheumatic pneumonia the lower part of the left lung was likely to be affected; in erysipelatous cases the lower part of the right lung was more generally attacked; while in catarrhal cases any part of the lung was liable to be affected; the congested or inflamed condition of the bronchial mucous membrane being liable to extend to the parenchyma of the lung.

Dr. J. SOLIS COHEN had not seen any erysipelas; but he had seen a few cases of pneumonia, and quite a number of cases of influenza. He believed that we had been going through a mild visitation of real epidemic influenza, a malady entirely different in nature from the prevalent catarrh so frequently miscalled influenza. His experience verified the observations of the older writers so carefully collected in Thompson's "Annals of Influenza," published by the Sydenham Society some twenty years ago. Though he had not observed all the varieties there mentioned, he had observed four special peculiarities of manifestation, sometimes occurring in different members of the same family, and traceable to the same cause. The first and most frequent form was principally catarrhal, affecting the nasal and bronchial passages and the pharyngeal and conjunctival mucous membranes. The second form affected chiefly the mucous membrane of the intestinal tract, and manifested itself by copious diarrhœa, sometimes colliquative, and sometimes attended with nausea and vomiting. The third form was cephalalgic or cerebral, and this form is said to be sometimes attended with erysipelas. The fourth form was a subacute metastatic rheumatism, with great soreness of the affected muscles and joints. All these varieties may be accompanied by intense suffering, severe fever, suppression of urine, etc. The

cases require a supporting treatment, and do well under it, the attack seldom lasting longer than a week. He had found it necessary to administer quinine in double and sometimes treble his ordinary doses, in order to produce the positive effects of the drug.

These epidemics affect animals as well as men, and it is probable that the catarrhal disorder so recently rife among horses was a manifestation of the same affection. In some epidemics the number of individuals attacked has equalled at least one-eighth of the entire population in the affected districts. He based the conclusion as to the identity of the different manifestations upon the fact that he had seen the several varieties at the same time, in the same house and family.

He stated that pneumonia in the northern and western portions of the city was chiefly of a typhoid type, though many stenic cases had occurred likewise; it had been unusually fatal, the patients succumbing in a very short time after seizure. He thought the epidemic cause inducing influenza might have something to do with the low type of the prevalent pneumonia.

Dr. STETLER said that, although his ward a year ago was severely visited by the smallpox epidemic, he was not aware, until he had come here this evening, that erysipelas and influenza were very prevalent in that locality at this time. He had seen pneumonia of a typhoid character, in which the most active stimulation, quinine, concentrated fluid nourishment, etc., had failed. He had also seen the disease in a robust man, in whom there was partial solidification, do well under cupping, calomel, tartar emetic, and Dover's powder. The so-called influenza he regarded as ordinary catarrh, due simply to atmospheric vicissitudes or the January thaw. He asked the members whether they often found pneumonia at the superior portion of the lungs in adults. Dr. STETLER referred to the fact that the Spruce and Pine Street Railroad Company lost about forty horses last year from a disease which caused the shedding of the hoofs and, of course, necessitated the killing of the animal. Those horses that were affected but did not lose the hoof remained weak and unfit for use for a long time. The cause was attributed to the laying of the planks in cement, and which, from a want of drainage, had become saturated with urine. As soon as the old floor was removed and proper drainage substituted, the horses convalesced. Strange to say, the epizoötic did not attack the horses in this stable.

Dr. WELSH had seen a number of catarrhal affections. He had seen four affected in the same family with influenza; two of them had croup, the babe diarrhœa, and the mother intermittent neuralgia, which was only partially relieved by quinine.

Dr. BURNS thought he could corroborate the remarks of Dr. Cohen, as he had seen gastro-enteric trouble, resembling an attack of cholera morbus, in a lady a few days since. He found her cold, lips and hands livid, pulse indistinct, vomiting, and abdominal pain. She had hoarseness and an irritating cough, but no pulmonary crepitus, although the respiratory murmur was indistinct and there was evidently congestion of the lung-tissue. The case was quite alarming, and more especially as she had cardiac disorder, the result of rheumatism which she had had several years previous. Bottles of hot water were ordered to the extremities and others placed near her body at different parts; sinapisms to the spine and sternum; internally, carbonate of ammonia, tincture of valerian, laudanum, and camphor-water made into a mixture, to be taken every half-hour, with brandy punch occasionally, constituted the treatment. To-day reaction has taken place and recovery seems established.

He had observed other cases in which diarrhœa has been connected with the bronchial irritation. Perhaps in these cases some idiosyncrasy was the cause of the metastasis from the bronchial to the enteric mucous membrane. These cases yielded to diaphoretic and tonic treatment similar to that stated above.

Dr. BAXTER had noticed the concurrence of respiratory and abdominal disease in several families, and could sustain Dr. Cohen in calling them different forms of the prevalent influenza.

Dr. BURPEE had seen influenza and diarrhœa in the same family. Diarrhœa seemed prevalent in children. It seems to be due to a common cold with fever accompanied with extreme depression. He gives large doses of quinine combined with capsicum. In many cases the throat and chest are affected, indicating a tendency to pneumonia. In some cases obstinate coryza was present.

REVIEWS AND BOOK NOTICES.

ILLUSTRATIONS OF THE INFLUENCE OF THE MIND UPON THE BODY IN HEALTH AND DISEASE. Designed to Elucidate the Action of the Imagination. By DANIEL HACK TUKE, M.D., M.R.C.P., etc. 8vo, pp. 415. Philadelphia, Henry C. Lea, 1873.

This admirable contribution to the science of mental physiology and pathology is addressed, says the author, to both medical and non-medical readers; and we cannot but think that the latter class will find as much to interest and profit them as the former. Dr. Tuke's style is so singularly clear, and his topic one so strongly appealing to every intelligent mind, that few will take up his book without becoming absorbed in its pages. He especially hopes that his lay readers "may be disposed to regard in a different light from what they may heretofore have done, the success of some of the fashionable modes of treatment current at the present day. Some of those, also, who are interested in the manifestations of modern Spiritualism, may find it worth their while to acquaint themselves fully, in the first instance, with those phenomena which may certainly be explained by a reference to the principles laid down in these pages."

The subject-matter of the work is arranged in four parts, comprising eighteen chapters. Part I. treats of the intellect, its influence on sensation, on the voluntary and involuntary muscles, and on the organic functions. In Part II. the emotions are discussed, and their influence on the same phenomena and agents, with a separate chapter on the question, "Do mental states, especially the emotions, act indifferently upon the several organs and tissues of the body?" The answer to this question is formularized as follows (p. 311): "While the intellect confines its operations mainly to the brain, although capable of exciting motion and the organic functions, the emotions act with by far the greatest force upon the heart and lungs, the vessels and the glands; and the will, powerless in regard to these tissues and organs, exerts its influence over the muscles engaged in the motions of the body."

Part III. is taken up with the will and its influences, and Part IV. with the influence of the mind upon the body in the cure of disease.

An analysis of the principal illustrations given in this book, a list of the principal works referred to, and a copious index, add greatly to its value.

CONTRIBUTIONS TO MENTAL PATHOLOGY. By I. RAY, M.D., Author of "Medical Jurisprudence of Insanity," and "Mental Hygiene." 8vo, pp. 558. Boston, Little, Brown & Co., 1873.

All but two of these papers have already appeared in print; twelve of them in the *American Journal of In-*

sanity, between 1836 and 1867. Several of them are analyses of murder-trials in which the plea of insanity was set up; several others are analyses of cases in which wills were disputed on the same ground. The papers on "Doubtful Recoveries," on "The Law of Insanity in Criminal Cases," and on "The Confinement of the Insane," seem to us of special interest. Another, which merits the careful study of lawyers as well as of physicians, is that on "Medical Experts."

The last three essays, on "The Insanity of King George the Third," on "Shakspeare's Illustrations of Insanity," and on "Illustrations of Insanity by Distinguished English Writers," are full of evidence of the author's profound knowledge of his subject, and of the delicacy of his powers of analysis. To the general reader, these would be by far the most attractive portions of this book.

Dr. Ray brings to his work a very wide experience, a logical habit of mind, and a pure and elegant style. We only fear that the desultory character of this collection of papers will in some measure prevent its obtaining from the profession the attentive perusal which it well deserves.

BOOKS AND PAMPHLETS RECEIVED.

The Medical and Surgical History of the War of the Rebellion (1861–65). Prepared, in Accordance with Acts of Congress, under the Direction of Surgeon-General Joseph K. Barnes, United States Army. 2 vols. 4to, pp. 1134 and 819. Washington, Government Printing-Office, 1870.

Club-Foot: its Causes, Pathology, and Treatment. Jacksonian Prize Essay for 1864. By William Adams, F.R.C.S., etc. With One Hundred and Six Wood Engravings, and Six Lithograph Plates. Second Edition. 8vo, pp. 464. Philadelphia, Lindsay & Blakiston, 1873.

Notes on Asthma: its Nature, Forms, and Treatment. By John C. Thorowgood, M.D. Lond., etc. Second Edition. Crown 8vo, pp. 166. Philadelphia, Lindsay & Blakiston, 1873.

Nineteenth Annual Report of the Medical School (Boston) of Harvard University, 1872–3. (Reprint from the Catalogue of the University.) Crown 8vo, pp. 22. Cambridge, Charles W. Sever, 1873.

GLEANINGS FROM OUR EXCHANGES.

Women and the Study of Medicine (Rector's address, by Dr. Josef Späth, delivered November 12, 1872: quoted from the *Wiener Mediz. Presse*, December 1, 1872).

In the opinion of Dr. Späth, women are intellectually able to study and practise medicine, but he thinks the great question is not in respect to their intellectual ability, but to their physical suitability for such a life. In this connection he says, "The intellectual capacity of woman cannot decide her course respecting the practice of medicine, but we must first of all consider the natural law that every creature has a particular mission to fulfil in the creation, is created for a special object; and the creature is complete only when in perfect harmony with the object of its creation.

"This law applies to man as part of creation; and it is long since established that the prosperity of society depends upon each individual's performing that part for which his peculiarities fit him. If we make but a brief comparison between the male and female being, we shall soon be able to decide whether both have the same place assigned to them, and whether both are likely to be able to perform the same functions in the same places in society.

"That the females should expect or be expected to perform duties similar to those of man in respect to the medical profession is impossible, from the delicacy of females between the ages of ten and twenty-five years. During this period their sexual life demands so much care that the student life pursued by boys and young men of corresponding ages would be too much interrupted, even if it could be endured, to make the necessary progress in scientific studies to prepare them to be physicians." This is the most practical part of the discourse. He then says, "Prudential as well as ethical motives prompt us to separate the two sexes, at the age already mentioned, to such a degree as to interfere with their studying together in the same lecture- and recitation-rooms of the university, and so far the institutions founded for women exclusively are, and can be, but superficial. Especially must I raise my voice in warning against the foundation of institutions for the education of half-physicians (*Halbheiten*), who benefit neither science nor mankind. And such are some of the institutions already established for women exclusively.

"But shall we render science inaccessible to woman, closing to her forever the secrets which science reveals?

"If the advancement of science is not the object of woman's existence, she still has a claim upon its revelations by virtue of the universal law of human rights, and we cannot refuse to impart to her all which science teaches, without an injury to humanity.

"Only by the torch of wisdom will prejudice and superstition be banished from the very nursery; an important advance, as each will admit when he recalls how difficult it is to eradicate prejudices and superstitions which have been instilled into the bosom of childhood.

"Educate women, lay before them the discoveries of science, not that they may pursue it as an avocation, but to fit them for their calling,—viz., that of educating the young, tender, and pliable beings intrusted to their care. Their dignity, their true worth, will indeed, in that event, be no less than if they were workers in the immediate field of science; for the corner-stone is no less valuable, because hidden, than the cap-stone, which sparkles in the sunlight on the gable. Men, yield not your ground. Women, do not strive against the laws of nature; for such conduct never goes unpunished. If women wish to be men, they may strip themselves of their feminine sex, but they still are not men.

"And can their dignity be augmented by such a strife? Can they obtain any advantage from it? Never! We admire the notes of the nightingale, we are amazed at the bold flight of the eagle towards the sun; but neither gains by attempting the *rôle* of the other."

Arterial Transfusion (*Berlin. Klin. Wochenschr.*, Dec. 23, 1872).—In the clinic of Prof. Esmarch, of Kiel, transfusion has been tried recently in two cases.

The first was that of a little girl 12 years old, suffering with chronic suppurative ostitis of the tarsus. Amputation was performed, followed by repeated hemorrhages. The femoral artery was ligated underneath Poupart's ligament, and, although after the ligation hemorrhage ceased, the strength of the patient did not increase, and, although she was stimulated freely, the pulse remained weak and frequent. Transfusion was immediately proposed, and 250 cub. cm. of blood from two midwives were injected into the brachial artery of the right arm. During the transfusion the patient was not under the influence

of any anæsthetic. The effects of the transfusion were instantly seen to be of the most satisfactory nature.

The patient expressed herself as satisfied, as feeling warm and hungry. Her cheeks lost their paleness and became rosy, and her eyes grew brighter. The pulse, which before the operation was weak and beating 160 per minute, fell during the operation to 136 per minute. After the transfusion the artery was ligated peripherally and centrally, and the wounded portion was excised.

In three months the patient had recovered from both amputation and transfusion.

The second case in which transfusion was tried was one of retromaxillary pulsating fibroma teleangiectaticum. Langenbeck's ergotine injection was tried, with no favorable results. Great hemorrhages ensued, partial gangrene of the tumor, and high fever. Subsequently, osteoplastic resection of the superior maxilla, with preliminary tracheotomy, was performed, accompanied by simultaneous transfusion into the brachial artery. The result was fatal. In this case the amount of blood injected was 600 cub. cm., and, as in the preceding case, some few spots of extravasated blood showed themselves upon the arm through which the transfusion was accomplished. The artificial respiration in the latter case, in which tracheotomy entered into the operation, was kept up by Trendelenburg's method.

The man from whom the blood was taken to supply the demands of the transfusion subsequently passed through a long series of sufferings on account of his loss, the history of which is promised in a future communication from the clinic of Kiel.

Extra-Uterine Pregnancy (H. Lionville: *Le Mouvement Médical*, January 11, 1873).—A woman, 33 years of age, was admitted into the Hôtel-Dieu, under the care of M. Béhier, complaining of pains in the lower part of the abdomen, and constipation. Several days after her admission the pains became more intense, and vomiting of a slightly stercoraceous character occurred. Peritonitis supervened, with a predominance of symptoms on the left side. The patient was believed to be suffering from intestinal obstruction. Death soon occurred. At the autopsy, hemorrhagic peritonitis was found with masses of blood enclosed by bands of recent formation. More careful examination revealed a tumor of some size, which, on section, was found to be composed of clots of blood and membranes enclosing a fœtus of about the sixth week. The hemorrhage had occurred around the fœtus. The ovum was situated within the peritoneal cavity, bound down on the left side, and entirely free from the ovary. M. Güeniot states that in such cases, the pregnancy being in the earlier stages, a faulty diagnosis is to a certain extent the rule.

MISCELLANY.

The funeral of the late Dr. Hugh L. Hodge took place on Saturday, March 1, and was very largely attended by his professional brethren.

At a special meeting of the College of Physicians of Philadelphia, held Feb. 28, 1873, the following resolutions, offered by Dr. A. Stillé, were unanimously adopted:

Whereas, We have heard with profound regret that our venerable colleague, Dr. Hugh L. Hodge, has died, after a very short illness, while he was still in the full possession of mental vigor and actively engaged in professional duties; and

Whereas, It is due to his memory, and is a solace to our own regret, to place on record our estimation of his character and services: therefore,

Resolved, That by the death of Dr. Hodge the medical profession has lost one of its brightest ornaments and most valuable members; a teacher whose learning, eloquence, and wisdom rendered him one of the most eminent and useful professors of the medical school he so long adorned, and of the professional literature to which he contributed the results of his matured experience and reflection; a practitioner sagacious, skilful, and wise, who to the latest day of his life devoted his powers with rare success to the alleviation of suffering and the preservation of life, and secured the affectionate veneration of all whom he served; a man who, from the beginning to the end of his career, was not only pure and without reproach, but in every relation distinguished by singular conscientiousness and an earnest piety, and by a dignity of demeanor and consistency of conduct which made his name synonymous with truth and virtue.

Resolved, That Dr. H. Lenox Hodge be requested to prepare for the College a memoir of his late father; and that the College will pay the last honors to their distinguished Fellow by attending his funeral in a body.

Resolved, That the Secretary cause a copy of these proceedings to be transmitted to the family of Dr. Hodge, and published in two of the medical journals and in the daily papers of this city.

John H. Packard, *Secretary*.

At a meeting of the graduating class of the medical department of the University of Pennsylvania, held February 28, a committee, consisting of Messrs H. Estrazulas, C. M. P. Scott, W. Preston Snyder, W. I. Baker, and John Keating, was appointed to draft resolutions expressing the sentiments of the class in regard to the death of Dr. Hugh L. Hodge:

Whereas, We have heard with deep regret of the death of the late venerated Dr. Hugh L. Hodge, Emeritus Professor of Obstetrics in the University of Pennsylvania:

Resolved, That in the demise of Dr. Hodge, we, the younger members of the medical profession, deplore the loss of a kind sympathizing friend, a model of every virtue and professional attainment which could illustrate our noble profession.

Resolved, That we sincerely condole with his afflicted family in their bereavement, and, as a mark of respect to the memory of our departed professor, we appoint a committee to attend his funeral.

Resolved, That a copy of these resolutions be sent to the family of the deceased, and that they shall also be inserted in two daily papers and in the medical journals of this city.

John G. Schenck, *President*.
William H. Rush, *Secretary*.

It is stated in the *Revue Scientifique* that the Swiss Society of Natural Science ("Société Helvétique des Sciences Naturelles") consists actually of nearly nine hundred members, besides over one hundred honorary

members chosen from among the chief scientific notables in other countries. Several of these foreign *savans* attend the annual meetings. Their presence was especially noted at the session of 1865, at Geneva, when, under the presidency of M. A. de la Rive, the Society celebrated the fiftieth anniversary, or a sort of semi-centennial jubilee, of its foundation. On that occasion there were attracted, besides an unusually large number of native members, Dumas, Claude-Bernard, Henri Deville, Descloiseaux, Martins, Lissajous, Rouget, etc., from France; Wöhler, Kölliker, Dove, Magnus, De Bary, Oppel, etc., from Germany; Tyndall, Frankland, Sir J. Lubbock, Ball, and others, from England; Volpicelli, Cornalia, Capellini, Omboni, from Italy; Steenstrup, from Denmark; and many others who might be named, from America and the East Indies,—in all, nearly a hundred foreign members having registered themselves.

During the past fall and winter, Dr. W. W. McClure, Surgeon to the Wills Hospital, and Ophthalmic Surgeon to the Presbyterian Hospital, has been delivering an interesting course of lectures on Ophthalmology in the Chant Street Lecture-Room of this city. These lectures have been very successful, attracting unusually large classes every evening; and they are especially noticeable from the fact of the oxy-hydrogen stereopticon having been employed throughout the entire course in illustration of the various points in anatomy, pathology, etc., brought before the class. The concluding lecture of the course was given on Tuesday evening, February 11, in the Chapel of St. Stephen's Church, which was filled with an attentive and appreciative audience of students and physicians.

Dispensary for Skin Diseases.—The Second Annual Report of the Dispensary for Skin Diseases, 216 South Eleventh Street, has just been issued. It states that during the past year there were 401 new patients admitted, and 2288 visits from time to time made at the dispensary. The average daily attendance of patients was 7. Of the whole number 196 were males and 205 females. The adults numbered 336, children 65.

It is in contemplation to make an effort to raise funds for the erection of a hospital building for this charity, which is at present under the following management: President, Samuel D. Gross, M.D.; Secretary and Treasurer, Henry A. Duhring; Physician-in-Charge, Louis A. Duhring, M.D.; Assistant-Physician, Arthur Van Harlingen, M.D.

Another Obstetrical Journal.—By an announcement just received, we are informed of the proposed publication, by the Messrs. Churchill, of London, of the *Obstetrical Journal of Great Britain and Ireland*, a monthly of sixty-four pages, to be under the editorial control of Dr. Aveling, of Dublin, and Dr. Wiltshire, of London.

The number of memoirs placed in competition for the "prix d'Ourches," for a test of actual death, is stated by the *Revue Scientifique* to have reached ninety; with the comment, "This 'concours' bids fair to develop more candidates than new tests."

Sir Henry Holland speaks of a nobleman who, when remonstrated with by his family for employing an illiterate physician, replied that "he thought a man who was so profoundly ignorant of everything else must certainly know a great deal about medicine."

A bill is before the Legislature of this State, looking to the examination of dental practitioners, by a Board to be appointed annually by the Pennsylvania Dental Society. Five dollars is fixed as the examination-fee, and twenty-five as the license-fee.

Dr. Thomas Maceuen, of this city, who died on the 27th ult., in the seventy-fourth year of his age, was a man of high literary and scientific attainments. He had for very many years retired altogether from professional life.

The Annual Commencement exercises of the Philadelphia Dental College were held on the 28th ult. The address to the graduates was delivered by Prof. John H. McQuillen.

Mortality of Philadelphia.—The interments reported at the Health Office for the week ending March 1, 1873, were 352; 201 adults, and 151 minors. 9 were of bodies brought from the country; making the mortality of the city 343. Among the assigned causes of death were:

Consumption of the Lungs	55
Other Diseases of the Respiratory Organs	50
Diseases of the Circulatory Apparatus	17
Diseases of the Brain and Nervous System	59
Diseases of the Digestive Apparatus	17
Zymotic Diseases (2 from Smallpox)	26
Typhoid Fever	2
Casualties	14
Cancer	7
Exposure	2
Intemperance	1
Gout	1
Debility (including "Inanition" and "Marasmus")	31
Still-born	21
Old Age	18

(The interments reported for the week ending March 2, 1872, were 436.)

The meteorological record kept at the Pennsylvania Hospital was as follows:

	Thermometer. Max.	Thermometer. Min.	Barometer. (2 P.M.)	
Feb. 23	22.0°	11.0°	29.89 in.	
" 24	19.5	1.0	30.02 in.	
" 25	30.5	17.0	30.11 in.	
" 26	35.0	28.0	30.20 in.	
" 27	43.0	31.0	29.86 in.	(Light Snow.)
" 28	34.0	24.0	30.20 in.	
Mar. 1	35.0	24.0	30.36 in.	

The mean temperature of the month of February was 30.57°.

SATURDAY, MARCH 15, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

LECTURE IV.

(Continued from page 355.)

ŒDEMA of the larynx is a very serious affection, on account of its liability to produce suffocation. Such a result has been known to occur at the very first evidences of the attack, before there had been any opportunity of establishing a diagnosis. Hence it is essential to be able to recognize the condition promptly and to treat it efficiently, lest temporizing treatment may sacrifice a patient whose life ought to have been saved. The obstruction in breathing is at first limited to inspiration, and is caused by the atmospheric current pressing inwards the tumid folds of membrane; but, as the disease progresses, expiration also becomes impeded.

When the œdema is dependent on acute disease, the suffocative paroxysms will be abrupt, violent, and occur irregularly at intervals of a few hours. When it is the result of chronic disease, the dyspnœa gradually increases until it culminates in a paroxysm of suffocation, which passes off with more or less relief to the respiration, to recur, as the disease progresses, at irregular intervals, which steadily grow shorter, until several paroxysms occur within the twenty-four hours, being, as a rule, more violent at night than in the daytime. In sub-glottic œdema the breathing is apt to be still more noisy, much like that occurring in laryngismus stridulus.

The best treatment for œdema of the larynx consists in making incisions into the swollen tissues. This affords egress to the pent-up fluids, and generally arrests the threatening symptoms immediately. This operation may be performed readily with a long curved bistoury, protected to within a short distance of its point, and directed to the parts by the guidance of the finger upon the seat of swelling. When the laryngoscope can be employed, Gibb's or Tobold's laryngeal knife affords much greater security in operating, and in great measure obviates the danger of wounding parts that should not be cut into. The spasm produced by the operation is usually insignificant. There is not, as a rule, much blood lost; but occasionally the bleeding is profuse, requiring the most assiduous efforts on the part of the patient to expectorate the blood entering the larynx, so that, despite the relief to the general dyspnœa, the patient has to cough for his life. The external and internal application of ice for a few minutes will generally suffice to restrain any alarming bleeding. Where the bleeding is but slight, it is often to be encouraged by a warm-water gargle or the inhalation of steam. After scarification the parts as seen in the laryngoscope present a wrinkled appearance, with bloody marks of the incisions.

A second scarification in cases of acute œdema is rarely requisite, especially when the progress of the disease can be watched with the laryngoscope, so as to be combated by less serious measures; but where the œdema is the result of chronic affections of the larynx, the operation may have to be repeated frequently. If the infiltration has made progress towards solidification, as sometimes happens, this operation will be ineffective, as it is only when the effused products are fluid that they can escape through the incisions. Under these circumstances, should the urgent symptoms of the condition persist, unmodified by the local results of the scarification,—such as the hemorrhage attendant upon it, the relief of the tension, etc.,—the operation of tracheotomy should be performed. This will save the patient for the time being, and allow him eventually to recover if there has been no fatal congestion of the lungs or brain, for the operation does not always succeed in rescuing the patient. Two instructive cases of this kind, followed by fatal results, are recorded by Drs. Pitman and Page.* The impeded respiration, if the operation be delayed, will have prevented due arterialization of the blood, and have thus induced congestion of the brain; a condition from the effects of which the patient may be unable to rally, even though he survive for a few hours, perhaps days, without further impediment to respiration. To be successful, it is almost essential that the operation be performed before congestion of the lungs has set in.

The trachea should be opened in preference to the larynx, in consequence of its greater distance from the seat of the disease, as well as for the reason that the disease may be extending low down in the larynx, and therefore exist at the very point usually selected for laryngotomy. Having thus by tracheotomy saved the life of the patient, scarification of the œdematous structures may be pursued more deliberately. This will be especially necessary if the tumefaction interferes with deglutition. Under circumstances of great urgency there ought to be no hesitation in opening the trachea with a pocket-knife, if no surgical instrument is at hand, and without any dissection, the delay for which may result in the loss of the patient.

Rupturing the bladder-like swelling by a smart stroke of the finger at the moment of examination has been recommended by Prof. Stromeyer. The epiglottis, when involved, may be firmly pressed against the root of the tongue, and would be very apt to suffer rupture of its attenuated mucous membrane under a vigorous stroke of the finger.

Where scarification or pressure fails to give immediate relief, tracheotomy should be resorted to

* *Lancet*, April 21, 1860.

at once, for the disease threatens death by suffocation before any impression can be made by ordinary antiphlogistic remedies; although there are a number of cases on record that have recovered under antiphlogistic measures. Catheterization of the larynx, which has been proposed for the purpose of promoting absorption, generally fails in affording any relief. Trousseau* has recorded a severe case of œdema of the larynx which was promptly relieved by inhalations of tannin; narcotic inhalations sometimes have a very happy effect. But treatment by inhalations is very rarely applicable, and not at all so where the symptoms are urgent. In one of the cases referred to, it was not employed with the hope of a favorable result, but as a means of temporary alleviation while in quest of a scarifying instrument.

In cases of but moderate severity, where the progress of the morbid process can be continually watched by the aid of the laryngoscope, the application of ice externally, and the continuous use of ice in the mouth, will sometimes effect an absorption of the effusion, and thus avoid any necessity for the use of the knife.

The œdema which occurs during the progress of chronic laryngeal disease usually sets in gradually, rarely insidiously, and may continue for a long period without producing any suffocative paroxysms, even when the entrance into the larynx is very much narrowed by the tumefaction. It seems as if the system accustomed itself to a gradual narrowing of the air-passages on the one hand, while on the other the general ill health of the patient and the lack of active exercise appear to lessen the demand for a large supply of oxygen. Certain it is that an amount of œdema is tolerated in chronic affections of the larynx which would cause symptoms of suffocation if it occurred suddenly in a healthy subject.

The œdema is more apt to be confined to one side than in the acute variety, probably because the laryngeal affection which produces it is often one-sided. Sometimes the condition is due to disease of the laryngeal cartilages, which have undergone caries or necrosis. The cricoid cartilage and the arytænoids are the most prone to become diseased in this manner; but the other cartilages do not possess any immunity from destruction. Ryland† mentions a case in which this was consequent on an attack of glanders contracted nearly a year previously; and in which dissection after death showed that the inner layer of the cricoid cartilage had undergone ossification, had become carious, and was partially loosened. Sometimes the detached and dead portions of cartilage are expectorated in coughing, and occasionally the sequestrum has been seen by means of the laryngoscope and then removed with forceps; and if any difficulty in detachment presents itself, tracheotomy may be necessary to remove the obstruction.

Scarifications, followed by the topical application of astringent solutions, such as solutions of nitrate of silver, sulphate of copper, chloride of zinc, chloride of gold, etc., with emollient and narcotic inhalations, constitute perhaps the best treatment. Blisters and other counter-irritants rarely do good, and are often productive of injury.

Opening the trachea for the mere purpose of setting the larynx at rest in chronic affections, as formerly advised by some, is rarely justifiable; for the affection terminates in death, and the respite is hardly worth its cost; besides which, the trachea is often entirely free from disease, unless congestion is excepted, and the condition of the lungs is usually such as to be in itself productive of all the phenomena of dyspnœa and cough. Under such circumstances the operation can hardly do more than actually add to the existing evils already endangering the remnant of the patient's life.

SUB-GLOTTIC ŒDEMA OF THE LARYNX.

The opinion has long been held by pathologists that œdema of the larynx could not occur below the glottis, on account of the close adherence of the mucous membrane to the perichondrium of the cartilages below the vocal cords. On the sides of the cricoid cartilage, however, there is a certain amount of distinct areolar tissue, which is sometimes sufficiently relaxed to permit the accumulation of exudative products, these being lymph rather than serum; though serous infiltration undoubtedly occurs in certain instances. This effusion is not an extension of the œdematous infiltration already present above the glottis, and, though occasionally coexisting with œdema above the glottis, usually occurs independently of any analogous condition in the ordinary localities of œdema in the upper portion of the larynx.

Sub-glottic œdema is an exceedingly rare affection. It has been recognized as an independent affection only since the employment of the laryngoscope in medicine; and the use of this instrument affords the means of certainty of diagnosis. We are indebted to Dr. Gibb, of London, for prominently calling the attention of the profession to this subject, which he has discussed at some length in the second edition of his work "On the Throat and Windpipe."

This form of œdema is sometimes produced by acute laryngitis, and the laryngitis of erysipelas, but also occurs in the course of chronic laryngitis of phthisis and syphilis; resembling in these respects the ordinary forms of œdema of the larynx.

As this subject is one not generally understood, and as a knowledge of the existence of sub-glottic œdema would have a considerable influence upon the locality to be selected for performing the operation of tracheotomy, in case such a procedure should become necessary, it may not be amiss to call attention to the cases detailed by Dr. Gibb. Dr. Gibb has collected, in all, evidence of eighteen instances of this affection, most of the material having been found at hand in the London hospitals. He states that "it may be taken as a rule that swelling never extends farther than the first ring of the trachea."

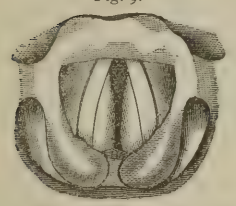
The subjective symptoms of the affection are similar to those of acute laryngitis, with those of

* Clin. Méd., Paris, 1861, p. 475. † On the Larynx, p. 42.

the ordinary forms of œdema; but the breathing is more stridulous and wheezing, and has a croupy hoarseness. There is great dyspnœa, cough, and an abundant secretion of mucus, rings of fibrinous sputa being sometimes expectorated. Symptoms of dysphagia are not manifested unless there be coexistent œdema of the upper part of the larynx, nor is there more marked stridor in inspiration than in expiration.

Laryngoscopic examination reveals projecting pads of mucous membrane bulging forward to the right and the left, below the vocal cords, and encroaching upon the transverse calibre of the larynx. (Fig. 9.)

Fig. 9.



Sub-Glottic Œdema of the Larynx.

Sub-glottic œdema is much more menacing to life than supra-glottic œdema; it is not so amenable to scarification and other topical treatment; not alone from the position of the effusion, which is below the glottis and therefore far more difficult to reach with instruments, but also because the effusion is not serous merely but fibrinous, and thus much less likely to be discharged through the incisions, even if the swelling could be scarified. The discharge of a serous effusion in the upper portion of the larynx, moreover, is assisted by the pressure exercised in the spasmodic contraction of the muscles, which follows the operation,—a result which there is no means of obtaining when the effusion is below the glottis and therefore out of the range of muscular compression. Tracheotomy is the only resource in severe cases. In cases of moderate extent and severity, the same remedial agents may be employed as in supra-glottic œdema; and from the fibrinous nature of the effusion we can reasonably expect a more salutary influence from the effect of mercurial remedies.

The deposit of sub-glottic œdema is not always absorbed, even if the patient should be saved by a timely tracheotomy; and hence it has been necessary in some cases to maintain the opening patulous by the constant presence of the tracheotomy-tube.

HEMORRHAGIC ŒDEMA OF THE LARYNX.

Hemorrhagic infiltration of the sub-mucous tissues of the larynx, to which the name of hemorrhagic œdema is frequently applied, is generally the result of some traumatic injury of the parts; giving rise to sudden and often fatal stenosis of the larynx. The hoarseness, dyspnœa, and dysphagia do not differ from those presented in the ordinary forms of œdema, but are dependent in great part on the locality and quantity of the blood effused. Sestier* relates a case in which the hemorrhagic effusion into the right ary-epiglottic fold followed upon a suicidal cut into the thyro-hyoid membrane, and caused a fatal termination by suffocation upon the fifth day after the injury.

Hemorrhagic œdema may also result from other than traumatic causes. Thus, Sestier† mentions the post-mortem appearances of hemorrhagic œdema in the ary-epiglottic folds, which occurred in the course of hemorrhagic smallpox. Rühle‡ gives a case of Pfeufer's. A man æt. 43, in freeing himself from vermin by inunction with mercurial ointment, became salivated. One evening, at six o'clock, he became chilly; and very soon after a severe cough set in, which soon acquired a croupy character. Dyspnœa set in, with stridulous respiration, and gradually increased, produced cyanosis, and suffocated the patient at eleven o'clock. Upon post-mortem examination a sub-mucous collection of blood was found in the larynx directly below the right ventricle, of the size of a quarter of an inch, and 1–3‴ thick in several places. The blood was liquid, and the mucous membrane over it was swollen. Pfeufer attributed the hemorrhage in part to the alteration of the blood produced by the mercury, and in part to acute catarrhal laryngitis.

ORIGINAL COMMUNICATIONS.

A CASE OF STRICTURE OF THE RECTUM PRODUCING OBSTRUCTION — DEATH ON THE SEVENTY-FOURTH DAY.

BY RICHARD MOFFETT, M.D.,
of Philadelphia.

W. H. S., aged 19, of slender frame, nervo-lymphatic temperament; by occupation a baker; had enjoyed average good health prior to his eighth year. At this time he suffered from an attack of dysentery, accompanied with prolapsus. The intestine had protruded to the extent of two inches. The subsidence of the disease developed a chronic torpor of the bowel, ending in constipation of a peculiar character: the stools were flattened.

After an immoderate indulgence in raw chestnuts and cabbage, the bowels became obstructed, November 15, 1871. The patient came under my charge November 20. At this time his tongue was clean and there was no febrile reaction. The abdomen was somewhat tumid, and the right iliac region was the seat of a dull aching pain. I at once ordered a two-ounce emulsion of castor oil with laudanum, and subsequently two drops of croton oil. These not producing the desired effect, they were followed by injections. These were equally fruitless. Upon the seventh day of the obstruction Dr. R. J. Levis was consulted. By his advice, tobacco-smoke enemata were given, but without any result. The rectum was explored, both by the finger and by bougies, but no obstruction was detected. The patient's appetite now became capricious; at times ravenous, it would disappear, and absolute anorexia persist for days together. The tongue now become coated, and the breath offensive. The treatment

from this time was chiefly supporting, it being deemed inexpedient to persevere in attempts to secure purgation. The abdomen growing more tense, and the pain increasing, it became necessary to resort to anodynes.

On the thirty-seventh day Dr. D. Hayes Agnew was consulted, who, with Dr. Levis, advised puncturing the abdominal wall to relieve the distention. This was done by means of a small trocar and canula, when a quantity of flatus escaped. The question of abdominal section now presented itself as a last resort to overcome the obstruction, which had been located by the consultants in the right iliac region. The fact that the obstruction had proven so obstinate without any vomiting of stercoraceous matter pointed, it was thought, to a cause situated within the large intestine, while the pain in the right iliac region indicated its position. After mature deliberation, it was decided not to operate; for were the obstruction detected at the head of the colon, it would in all probability be irremediable, even after free exposure of the parts. Upon the forty-second day, at the suggestion of Dr. Agnew, large quantities of sweet oil were injected daily. Small liquid motions, averaging half an ounce, followed each injection, and a larger quantity, in amount about the same as would ordinarily be voided at a stool, was removed about every third day. It was hoped that by this means a favorable termination of the case would be secured. But by the fiftieth day his skin, which up to this time had remained dry, was covered by a clammy secretion. The urine became scanty and high-colored, and the distention of the abdomen, which had become enormous, induced dyspnœa by the pressure upward against the diaphragm. The tongue remained thickly coated; the breath was exceedingly offensive; the pulse, which had remained throughout at the normal standard, rose to over 120, and at times was intermittent. It now became evident that he was sinking. He lingered until January 29, 1872, the seventy-fourth day, when he died of exhaustion.

Autopsy, January 31.—Present Drs. Moffett, Hunter, and Allen. Body much emaciated. The abdomen was enormously distended,—circumference thirty-six inches. The intercostal spaces of the false ribs were greatly widened: that at the sixth measured one and a half inches. The usual incision in the median line of the abdomen was made by Dr. Hunter, who conducted the examination. A large portion of the descending colon protruded through the opening. A casual examination of the abdominal cavity revealed little else than an enormously-distended colon. The sigmoid flexure was conspicuously elevated, and occupied the umbilical and hypogastric regions. It overlapped and tended to press inward the head of the colon. The splenic flexure was very acute. The circumference of the gut at this point was less than at any other. The hepatic flexure was discolored by the gall-bladder in the usual manner. The latter viscus was moderately distended with bile. The small intestine was distended its entire length. The stomach was pressed upward, but was not enlarged. The other viscera presented no features of interest. The colon upon being removed revealed a stricture completely surrounding the rectum as it lay directly below the right sacro-iliac junction. The diameter of the stricture was about four lines. Below it, the rectum was of the normal calibre; above, it presented the appearance characteristic of the healthy colon. The latter portion of the intestine was filled with fluid fæces of a dark loam color and of a fetid odor. Very little flatus was detected. The following were the measurements as recorded:

From pelvis to seventh rib, 15 inches.
From clavicle to seventh rib, 7½ inches.
Girth of abdomen, 36 inches.
Circumference of caput coli, 14½ inches.
Circumference of hepatic flexure, 12½ inches.
Spleen 4½ inches long, 2⅓ inches wide.
Kidneys 4½ inches long, 2 inches wide.

TRANSLATIONS.

VON OPPOLZER'S LECTURES ON DISEASES OF THE ŒSOPHAGUS.

Being the latter portion of the first part of the second volume of Oppolzer's Vorlesungen über specielle Pathologie und Therapie, Erlangen, 1872.

Condensed from the German of Dr. Emil Ritter von Stoffella,

BY DR. J. SOLIS COHEN.

(Concluded.)

VI.

CANCER OF THE ŒSOPHAGUS.

Cancer of the œsophagus is either fibrous, medullary, or epithelial. It is usually primitive, existing by itself; rarely consecutive, or the result of the encroachment of cancer of an adjacent organ.

Primitive cancer of the œsophagus involves, most frequently, the lower portion of the organ, in the vicinity of the cardia; but Von Oppolzer has observed it quite frequently in the thoracic portion of the œsophagus. It appears as a circumscribed disease, as a rule; occasionally, only, being extended over a great portion of the œsophagus, or even its entire length. It usually involves the whole circumference of the tube, and produces in this way an annular stricture; not infrequently, indeed, effecting complete occlusion of the calibre of the canal. Intimate inflammatory adhesions with the adjacent parts are formed within the reach of the cancerous degeneration, especially with the anterior surfaces of the vertebræ. Above the cancerous constriction the œsophagus is distended for a certain extent; below it, on the contrary, it is collapsed; a condition which occurs in all varieties of œsophageal constriction.

Cancerous disease of the œsophagus always begins in the sub-mucous connective tissue, whence it soon extends to the mucous membrane, upon which it becomes still further developed. The cancer softens, and uneven ulcers are formed, circumscribed by infiltrated borders, and covered with ichor from bleeding fungous vegetations. The diseased process extends to the neighboring organs; and the ulceration and destruction gradually acquire increased dimensions, so that communications may become established in this way with the lungs, the trachea, the bronchi, etc. At the same time, the cancerous formation may develop within the neighboring arteries, the aorta, and pulmonary artery, or

may produce erosion of the coats of these vessels by its destructive action, and thus give rise to fatal hemorrhage.

The most prominent *symptoms* of cancer of the œsophagus are those of œsophageal stenosis. Even before these symptoms attract special notice, the patient will exhibit a continuously progressive deficiency of nutrition and a loss of physical strength. He becomes emaciated, complains of debility and more or less loss of appetite, and finally acquires that appearance which is designated as cachectic. After several months or more have passed with these symptoms, difficulty in swallowing begins to be experienced, similar in the main to that observed in stenosis of the œsophagus from other causes, but increasing more rapidly to a severe degree. If the dysphagia has progressed so far as to have induced vomiting and regurgitation of ingesta, the food returned is at first mixed with stringy mucus, and at a later date with blood, ichor, and, now and then, with broken-off fragments of the cancerous formation.

There is not any pain, usually, in the earlier stages of the disease, or else the pain is very insignificant, and is confined to a slight burning sensation, or a feeling of pressure beneath the sternum, or at the pit of the stomach. Later in the case, however, and particularly after each meal, pain is felt, often of the severest lancinating character. Finally, in special cases, there are radiating pains in the upper extremities, particularly in the region of the shoulders and between the shoulder-blades, and also along the course of the intercostal spaces. If the cancer occupies the lowest portion of the œsophagus, near the cardia, painful paroxysms occur not infrequently, which can hardly be distinguished from those of cardialgia. Finally, in the later stages of the disease, when softening of the cancer and partial breaking-up have occurred, the calibre of the œsophagus will become greater, and the difficulty of deglutition will be diminished for a time.

The *prognosis* is unfavorable. There is no case on record which has not terminated fatally. The average duration of the disease has been found by Lebert to be about thirteen months. Von Oppolzer has remarked cases which have given rise to thrombosis, principally in the veins; or to secondary inflammation of the brain, or to gangrene of the lungs, thereby hastening the fatal termination.

The *diagnosis* depends chiefly on the advanced age of the patient, his cachectic expression, the slow progression of the malady, and the circumstance that it can in no other wise be accounted for. Complete and undoubted diagnosis can be made only upon the discharge of broken-up portions of cancerous matter by vomiting or regurgitation.

The *treatment* by dilating the œsophagus with sounds is advisable only in the earlier stages of the difficulty in deglutition. As soon as softening has commenced, such proceedings are dangerous, inasmuch as the softened tissues may be readily penetrated. In such cases the nourishment of the patient must depend upon so-called nutritive enemata; though they do not amount to much, because their subjection to chymification is wanting; besides which, they often induce inflammation of the mucous membrane of the large intestine. If the pain is severe, narcotics must be resorted to.

The reader is referred, in addition, to what has already been written in connection with cancerous stenosis of the œsophagus.

FIBROMA, AND FIBROUS POLYPUS OF THE ŒSOPHAGUS.

Fibroid nodules of the œsophagus occur but very rarely. They are mostly of but small size, in which case they produce no disturbances, and consequently cannot be diagnosed.

Fibrous polypus of the œsophagus is a more important affection than fibroma. Remarkable cases of this nature have been described by Rokitansky and by Munro. The fibrous polypus of the œsophagus usually arises from the perichondrium of the cricoid cartilage, and hangs down within the œsophagus. It gives rise to all the symptoms which attend constriction of the œsophagus, and, in addition, may occasion hemorrhage. If the polypus is situated in the uppermost portion of the œsophagus, it may be felt by the exploring finger, and even be made visible on retching. If it is large, it causes a projection in the neck.

The *treatment* of fibrous polypus of the œsophagus is altogether surgical.

NEUROSES OF THE ŒSOPHAGUS.

CRAMP OF THE ŒSOPHAGUS.

Cramp of the œsophagus—also called *spastic stricture of the œsophagus*—seldom or never occurs as an independent affection of the nervous plexus supplying the œsophagus; that is to say, as a true neurosis. It often occurs as a symptomatic spasm. Thus, we observe spasm of the œsophagus in diseases of the brain and spinal cord, in hysteria and hypochondria, in severe mental affections, and above all in hydrophobia, in which malady it is the most prominent symptom.

Reflex spasm, also, is no infrequent manifestation; to which category we may refer those cases of œsophageal spasm which attend diseases of the uterus, stomach (especially cancer of the stomach), heart, or lungs. In many cases the spasm is caused by disease of the œsophagus itself; as, for instance, in cases of inflammation, the formation of ulcers, etc.; and it often happens that cases of dysphagia, which are mistaken for simple spasm of the œsophagus, actually depend upon organic disease of the walls of this canal.

Symptoms. — The spasm may affect the œsophagus alone, or the pharynx likewise. It sets in suddenly, lasts a shorter or longer time, after which it disappears, to return at irregular, or, in rare instances, at regular intervals. In many cases the spasm occurs—especially when it is a symptom of hysteria —only upon the swallowing of solid or fluid substances, warm or cold; or it may be only certain kinds of food and drink that produce the spasm. The cramp is sometimes painless, sometimes painful, sometimes connected with a sensation as of a ball sticking in the throat (globus hystericus), or with a feeling of squeezing together, etc. If the upper portion of the œsophagus and the pharynx are affected with the spasm, then the food is rejected as soon as the attempt is made to swallow it. If the cramp affects the middle portion of the œsophagus, then either the further progress of the bolus is prevented, or regurgitation takes place, either immediately or after a while. Finally, in those cases in which the cramp takes place in the lowest portion of the œsophagus, in the neighborhood of the cardia, the patient can swallow, it is true, but the ingesta are very frequently regurgitated; and at the same moment the spasm suddenly relaxes.

If the spasm of the œsophagus is especially intense, or if it occurs in an irritable, so-called nervous individual, then it not infrequently happens that it extends to the respiratory organs and produces dyspnœa, anxiety as to the result, palpitation of the heart, and even, in some instances, loss of consciousness.

If an attempt is made to introduce a sound within the œsophagus during the spasm, the instrument will be arrested at the point of stricture, and be more or less firmly grasped by the walls of the œsophagus; but if we rest a moment, the instrument can be usually pushed onwards, without much effort, and suddenly, for the

most part, or with a jerk. Sometimes, in the anxiety of the patient, or in the dislike which he manifests at the catheterization of the œsophagus, the spasm will relax at the very moment that the sound is introduced, so that it can be pushed forward at once, without any hindrance, clear on into the stomach.

The duration of an œsophageal spasm varies very much; it may last a few minutes only, or may continue for several hours. It even happens, in many cases, that the spasm holds on, unbroken, for several days; and may thus, if such paroxysms recur frequently, interfere with the patient's nutrition to a very marked degree.

When the spasm relaxes, it is either simply by permitting the onward passage of the bolus detained in the canal, or by its forcible ejection; followed by the escape of flatus, and the secretion of a peculiar pale, straw-colored urine (urina spastica).

The *diagnosis* depends chiefly on the sudden appearance of the obstruction,—mostly during a meal,—the marked change from a greater or less degree of dysphagia to completely normal deglutition; the presence of other nervous symptoms, and of some disease known to give rise to spasmodic manifestations. Finally, catheterization of the passage gives the most valuable information towards establishing the diagnosis.

It is possible that it may alternate with a commencing stenosis, or with a paralysis of the œsophagus; but the manner of occurrence, the exploratory evidence of the sound, and the further observation of the patient will readily prevent the falling into error.

The *prognosis* will depend upon the cause which has given rise to the spasm.

Treatment during the Spasm.—As the patient cannot swallow during the spasm, medicine must be administered by the rectum, or by the skin. We order enemata of chamomile, valerian, assafœtida, camphor, etc.; sinapisms to the pit of the stomach and the neck; or the inunction of an ointment of cicuta, hyoscyamus, opium, or belladonna, along the spine. Above all, the subcutaneous injection of acetate of morphia or of atropia is to be especially recommended, both on account of its simplicity and feasibility, and on account of its usually prompt success. Besides this, warm tub-baths, eventually in connection with cold sponging, are to be recommended in cases where the cramp has continued for a long time. As a still further and, in many cases, a remarkably successful method of overcoming obstinate spasm of the œsophagus, the proceeding of Mondiére is to be extolled in cases of great sensibility of the œsophageal mucous membrane; this consists in the introduction of a sound smeared with belladonna ointment. If the spasm continues a long time, it will be necessary, in addition to the therapeutic measures, to institute measures for nourishing the patient artificially, by injecting the nutriment through a tube carried down into the stomach.

Treatment during the Interval.—When the spasm has ceased, we resort to the internal administration of zinc, valerian, belladonna, assafœtida, or some of the other so-called nervines. If the paroxysms of spasm are periodic, or if they return with frequency, we resort, in addition, to the influence of the sulphate of quinine.

If there is any special fundamental disease on which the spasm is dependent, it should always receive the fullest recognition in the selection of therapeutic agents.

PARALYSIS OF THE ŒSOPHAGUS.

Outside of traumatic causes, paralysis of the œsophagus is most frequently due to disease of the brain, spinal cord, and par vagum (tumors especially); chronic lead-poisoning, hysteria, diphtheritis, syphilis; or to severe febrile affections, especially typhus. Further, paralysis of the œsophagus is said to follow deglutition of hot drinks; exposure to cold; and fright.

Symptoms.—There are several grades of this affection, varying from a slight paresis to complete paralysis. At the commencement the patient merely remarks that the bolus will not progress properly; repeated acts of deglutition, or the swallowing of water after it, being necessary to force it farther. Large mouthfuls are swallowed better than small ones, and solids better than fluids; and swallowing is performed much better in the erect than in the recumbent posture. Fluids pass down into the stomach with one or more sonorous movements, —a symptom designated as "deglutitio sonora" by the older writers. The difficulty in swallowing gradually increases, and neither the size of the bolus, nor its consistence, nor even the position of the patient, seems to have any influence on the want of facility in swallowing; and finally complete dysphagia exists.

The latter condition is principally observed when, as is not seldom the case, the pharynx is paralyzed as well as the œsophagus. There is no pain during the entire course of œsophageal paralysis, and only occasionally does it happen that regurgitation occurs. If the parts are explored by the sound, no obstruction is perceived at any point, and the instrument can be moved about in all directions.

Paralysis of the œsophagus is not infrequently complicated by paralysis of the pharynx, as already mentioned, but it is also associated, in some instances, with paralysis of the arms, the face, the tongue, the soft palate, the larynx, etc. The combination of paralysis of the œsophagus with paralysis of the tongue and of the larynx places the patient in a very wretched condition, which has been thus strikingly described by Hamburger: "When paralysis of the muscles of the tongue and of the larynx is associated with paralysis of the pharynx, there is always a paralysis of the respiratory muscles, rendering the last days of the patient's life the most torturing that can well be witnessed. At each attempt at deglutition, which must often be made on account of the great thirst or hunger, a portion of the matters pass into the larynx, without the power on the part of the patient to expel them promptly, on account of the great debility of the respiration. What martyrdom, for hours, to free the larynx once more! and hardly is this accomplished when the torture begins again, as every particle of saliva which should have been swallowed passes into the larynx. The last days of the patient present a spectacle of unspeakable distress. Bowed forward, with the saliva flowing unrestrainedly from his mouth, he sits fretted with constant coughing and hawking, debilitated by hunger and thirst, to utter inanition, until, finally, the heart unexpectedly stops of a sudden."

The *auscultatory evidences* of paralysis of the œsophagus are analogous to those of dilatation. It is, therefore, unnecessary to recapitulate them.

The *prognosis* is, in general, unfavorable; especially when the paralysis is not restricted to the œsophagus.

The *treatment* is to be directed against the original cause of the malady. If this treatment is unsuccessful, or if the cause cannot be determined, resort is made to electricity, to blisters or irritating ointments along the spine, to irritation of the œsophagus itself by the frequent introduction of the sound, to cold sponging in combination with frequent douching, and to the internal administration of strychnine, or its hypodermic injection when the former fails.

The nourishment of the patient must be conducted by means of the stomach-tube, if the paralysis is very great. If the patient is still able to swallow, mouthfuls that stick in the œsophagus during meals—as is so often the case—must be pushed down with the œsophageal probang.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 15, 1873.

EDITORIAL.

"BOGUS" DIPLOMAS.

ACCORDING to the published reports of the Pennsylvania Legislature, on March 4, 1873, in the House of Representatives,

"Mr. Josephs offered the following:

"*Whereas*, A Joint Committee of the Legislature in 1872, in accordance with instructions, made a report upon the sale of bogus diplomas in Arts and Medicine, and, in accordance with said report, the charter of the Philadelphia University of Medicine and Surgery was repealed, with the view of arresting the said sale and traffic in such degrees; and

"*Whereas*, It is believed that the traffic is still carried on, even to a greater extent than before, and that the Eclectic College and American University of Pennsylvania [Philadelphia], whose charters were repealed, are still in operation; and

"*Whereas*, The following advertisement is circulating in Europe:

"'Extracts from the Statutes of the University of Pennsylvania, of Honorary Degrees in Divinity, Law, Arts, and Medicine.

"'First. These may be conferred either at the instance of the Faculty, or in pursuance of a resolution of the Board of Trustees, but no such degree shall be conferred unless the mandamus ordering the same be signed by two-thirds of the whole number of trustees, nor unless the candidate shall have been nominated at the Board three months previous to taking the question on conferring the degree.

"'Second. The question of conferring an honorary degree shall always be decided by ballot, and the candidate must receive an unanimous vote.' And

"*Whereas*, The Mayor of Philadelphia has recently called the attention of the public to the fact that he has received from Europe information that bogus degrees are still a matter of merchandise, emanating from Philadelphia: therefore,

"*Resolved*, That a committee of five members of the House be appointed to investigate the Eclectic Medical College, the Homœopathic Medical College, the Jefferson Medical College, and the Pennsylvania University, together with all other colleges acting under the authority of the State, with power to send for persons, papers, and books, and who shall act without compensation.

"This resolution was urged by Mr. Josephs, who said that City Solicitor Collis had ascertained in Europe that the bogus diplomas were still issued.

"Mr. Mahon opposed the resolution, as being too broad, and as, in a measure, recognizing the existence of colleges whose charters had been repealed.

"The resolution was defeated by 32 yeas to 55 nays.

"Mr. Josephs offered a resolution instructing the Attorney-General to inquire whether the colleges whose charters were repealed in 1872 were still issuing diplomas.

"Mr. Josephs sent to the clerk a number of extracts from newspapers, showing that diplomas were still sold.

"Mr. Elliot (Speaker) held that the Legislature owed it to the people to protect them against quackery, and he could not see why any one should oppose the examination.

"Mr. Hancock said that the Legislature had repealed the charters, and could do no more.

"Mr. Elliot said that the law authorized damages to be found against railroads for killing people at the rate of $5000 per man. How many men would the quacks kill when armed with bogus diplomas?

"Mr. Hancock opposed investigating committees in general, and denounced the law which had limited railroad damages to $5000, as an outrage. He was really in favor. however, of the last resolution, instructing the Attorney-General to inquire into the matter.

"A running debate took place as to the best way of reaching the desired end, viz., the punishment of those who issue bogus diplomas.

"The following was finally passed:

"*Resolved*, That the Attorney-General be instructed to inquire whether any person or persons purporting to be officers of legally authorized medical colleges are issuing diplomas purporting to have the official seal of colleges whose charters have been repealed."

In connection with this subject, the following letters have been placed at our disposal, and we present them in their original language, with a translation, for the information of our readers:

No. 1.

MR. P. F. A. VAN DER VYVER,
DOCTEUR EN DROIT, JERSEY, ANGLETERRE.

24 Nov. 1872.

MONSIEUR,—En réponse à la lettre que vous venez d'écrire, j'ai l'honneur de vous informer que j'ai en mon pouvoir les moyens de vous faciliter l'obtention du diplôme que vous pouvez désirer de l'Université américaine de Philadelphie, dont je vous remets les statuts ci-inclus.

J'entreprends toutes les formalités à mes frais, risques et périls; ainsi vous obtiendrez votre diplôme sans vous déplacer.

La totalité des frais s'élève à six cents francs sans avoir autre déboursé à faire.

Je suis à votre service pour tout ce que pourra vous être utile et agréable, et vous prie d'agréer mes civilités empressées.

P. F. A. VAN DER VYVER,
46 Rue du Roi,
Jersey (Angleterre).

No. 2.

MR. P. F. A. VAN DER VYVER,
DOCTEUR EN DROIT, JERSEY, ANGLETERRE.

29 Nov. 1872.

MONSIEUR,—Je pourrais procurer à votre protégé ce qu'il a besoin et même plus, car je pourrais lui influencer les deux titres de Docteur de Philosophie et Bachelier-en-Lettres sur le même diplôme pour un seul honoraire de six cents francs y compris le certificat d'inscription.

Il y aurait aucun déplacement pour votre protégé à faire; vous auriez seulement à me satisfaire par votre correspondance, que le candidat possède les qualifications, et alors j'enverrai sa promotion au délégué de l'Université américaine à Philadelphie, et il est certain qu'il obtienne son diplôme.

Plusieurs personnes éminentes de Bruxelles et des départements ont déjà obtenu leur diplôme par mon entremise.

Recevez mes civilités empressées.

P. F. A. VAN DER VYVER.

Réponse au plutôt S. V. P. pour que la nomination se fasse vers la fin du mois de Décembre, quand la session actuelle termine et les examens auront lieu.

No. 3.

MR. P. F. A. VAN DER VYVER,
DOCTEUR EN DROIT, JERSEY, ANGLETERRE.

12 Déc. 1872.

MONSIEUR,—Il est surprenant que votre ami vous a tellement renseigné.

Il existe grand nombre de bonnes Universités dans les États-Unis, et notamment à Cambridge, Providence, New Haven, Philadelphie, Columbie, etc.

Il y a à Philadelphie 3 ou 4 bonnes Universités, dont l'Université de Pennsylvanie établie en 1755 occupe le premier rang, et l'Université américaine établie en 1840 occupe le deuxième en [*sic*] rang.

Du reste, vous trouvez dans l'almanach des adresses de Philadelphie, notre Université. Les diplômes, qui sont en latin, porte que l'Université possède le plein pouvoir d'accorder des diplômes.

Du reste, l'Université est établie depuis 40 ans; ainsi votre ami doit peu connaître la ville de Philadelphie pour ne pas se rappeler de cette Université.

Recevez l'assurance de mes bons sentiments.

P. F. A. VAN DER VYVER.

TRANSLATION.

No. 1.

MR. P. F. A. VAN DER VYVER,

Doctor of Laws, Jersey, England.

November 24, 1872.

Sir,—I have the honor to inform you, in answer to your late letter, that it is in my power to assist you in obtaining such diploma as you may desire from the American University of Philadelphia, a copy of whose regulations I enclose.

I will fulfil all the formalities at my own expense and risk, so that you will obtain your diploma without leaving home. The expenses will amount to six hundred francs, including everything.

I offer you my services for whatever may be useful or agreeable to you, and beg you to accept my sincere compliments.

P. F. A. VAN DER VYVER,
46 Rue du Roi,
Jersey (England).

No. 2.

November 29, 1872.

Sir,—I am able to procure for your friend all that he desires, and more besides, for I could obtain for him the two titles of Doctor of Philosophy and Bachelor of Arts upon the same diploma for the single fee of six hundred francs, including the expenses.

Your friend need not leave home; you will only have to assure me by letter that your candidate is properly qualified, and then I will forward his nomination to the agent of the American University of Philadelphia, and it is certain that he will obtain his diploma.

Several eminent persons in Brussels and in the departments have already received diplomas through my intervention.

Accept my sincere respects.

P. F. A. VAN DER VYVER.

Please to reply as soon as possible, so that the nomination may be made before the end of December, when the present session ends and the examinations will take place.

No. 3.

December 12, 1872.

Sir,—It is surprising that your friend should have given you such information.

There is a large number of good Universities in the United States, particularly at Cambridge, Providence, New Haven, Philadelphia, Columbia, etc.

At Philadelphia there are three or four good Universities, among which the University of Pennsylvania, founded in 1755, holds the first place, while the second in rank is the American University, established in 1840.

Moreover, you will find our University in the Philadelphia Directory.

The diplomas, which are in Latin, state that the University has full authority to confer diplomas.

Besides, the University has been established for forty years: so that your friend must have but little knowledge of the city of Philadelphia if he does not remember this University.

Accept the assurance of my friendly feelings.

P. F. A. VAN DER VYVER.

It will be inferred from one of these precious epistles, that of December 12, 1872, that Mr. Van der Vyver's correspondent must, on information received from a friend, have suggested some doubts of the genuineness of the "American University of Philadelphia." The accommodating gentleman thereupon expresses his surprise at such incredulity, and, in order to clinch the proof of his own veracity, transmits a photograph of the "University," and requests the correspondent "to ask his friend if he does not remember Pine Street, and the large building represented in the photograph." This "photograph" turns out to be the photograph not of the college itself, but of a wood-cut bearing the printed title "The American University of Philadelphia, 514 Pine Street, Philadelphia, U.S.A." It represents a double three-storied building with a French attic, with a large door in the centre, and in the second and third stories large triple windows above the door. Surmounting the roof is an ornamental balustrade; and from a lofty flag-staff the American flag waves over all.

Having no recollection of such an edifice in the locality, with which, however, we were pretty familiar, we made a pilgrimage to this Mecca of diploma-desiring aspirants; and, behold! no building even remotely suggesting the print was to be found. Two very old and plain three-storied brick dwelling-houses, each of them about twenty-two feet front, were the only representatives of the "grand bâtiment" of the honorable Mr. Van der Vyver. One of them is occupied by a manufacturer, not of "doctors," but of cabinet furniture; and over the door of the adjoining one, in brazen letters, is the inscription "Eclectic Medical College of Philadelphia;" and all around are tin signs setting forth what diseases are to be cured within. The "grand bâtiment" is simply a myth! —whether devised by the honorable Doctor of Laws of the island of Jersey, or by some of those astute natives who seem to care very little for the law, the legislature, or the attorney-general, is not certain. But it is high time that the power should not only be found, but should also be vigorously used, to crush out this brood of rogues, who seem to laugh at law, while they are dragging in the kennel the names of honest institutions and everything which honest men respect.

AN EXCELLENT MEASURE.

EVERY good citizen of the United States, and in fact every friend of purity and good morals everywhere, will hear with pleasure that a bill "to prevent the mailing of obscene books, papers, articles, and advertisements"—we quote from one of the daily papers—has passed both Houses of Congress and received the President's signature. Faithfully executed, such a law will be an incalculable benefit to the nation.

The nefarious business of scattering obscene publications is, if we are rightly informed, one which can be, or has been, carried on to advantage only through

the mails; since, for obvious reasons, there must be no direct contact between the actual producer and the buyer. We have had brought to our notice, from time to time within the last twenty years, a very large number of advertisements of vile books and pictures, not for sale at any given place, but to be had by sending the price to specified addresses. This practice can be attacked only by the general government, which alone can control the mails. It remains for each State to enact and execute such laws as shall protect its citizens from more direct and open offences against social morality.

It is perhaps hardly necessary to point out the bearing of such legislation, duly enforced, upon the public health. The evil effects of obscene books and papers in fostering the lowest passions, in promoting solitary vice, in debauching the pure, and in rendering the impure worse, can scarcely be over-estimated. By checking the publication of this vile rubbish, one of the great sources of immorality, of the physical and moral ruin of the young, and of venereal disease, insanity, and pauperism, would be cut off.

LEADING ARTICLES.

RECENT IOWA LEGISLATION CONCERNING INSANE HOSPITALS.

II.

IN the last number of the *Medical Times* we adverted to the distrust and suspicion apt to attach, in the public mind, to persons who have occasion to confine insane relatives, to physicians who recommend the step, and especially to all hospitals for the care of this unfortunate class. As one of the latest and most outrageous manifestations of this unjust and bitter spirit, we gave the substance of an act lately passed by the General Assembly of Iowa. We now propose to show the alarming and most mischievous tendency of the act, and to glance at the influences by which legislators were led so singularly to commit themselves.

No one will deny that one proper object of an insane hospital is to exert a certain control and government over persons who have either lost the power of self-control, or have ceased, in consequence of disease, properly to exercise it. In many cases of insanity—even in most—control is imperatively demanded, for the safety of the patient, of his friends, and of his property, and for the peace and order of society. Such restraint, of course, abrogates for the time personal liberty. This is unavoidable; and the only question is, how this coercion can be exercised with the greatest comfort and security to patient, family, and society, and with the best prospect of ending its need by cure. At home, any attempt to govern is fiercely opposed or peevishly complained of. Accusations of ingratitude, loss of natural affection, oppression, or cruelty, are freely made. Reproaches, added to the already distressing grief, sympathy, and agitation of the friends, cause their measures of control to be fitful, injudicious, and irritating. Tears, upbraidings, entreaties, fierce denunciations, and excited appeals, met by equally passionate avowals of sympathy, and by useless reiterations of argumentative attempts to make the insane man feel and think as if he were sane,—these things make the lives of most insane persons at home, if not utterly demented, scenes of perpetual wrangling and contention, leading almost surely to chronic, life-long derangement. The sane relatives are certain to suffer terribly in mind and body from the ever-present sorrow, the strife, and the sleeplessness.

On the other hand, let the same patient be placed, without deception, in a hospital early in the disease. He may resist, use violent and bitter words, and breathe vengeance on all concerned. Still, he is there, and the door is closed. He sees others around him conforming their lives to rule and system. He is treated courteously and kindly by officers and attendants. He perceives that they consider him, not as a prisoner to be punished, but as a sick man to be cured. They have no connection with his home-troubles, and hence provoke no bitter feelings. If at first, or at times, he be violent and abusive, he is met only with a few kind, firm words, or gentle but efficient restraint. He is indulged in no heated discussion. If he write angry letters to his family, he receives no answer; and the fires of his wrath die for want of fuel. If not furiously maniacal, he recognizes the power of his physician as absolute and inevitable. The hospital is a ship, and the superintendent its captain, whose supremacy is unquestioned. The patient thinks it all wrong for him to be there; he is not insane; he would have got along perfectly well at home if they had only let him alone; he was only a little nervous, or harassed by business, or angered by the disobedience or interference of wife or child. Still, in point of fact he is calm and tranquil, as compared to his state at home. The mental splints are upon the broken mind, and the conditions favor cure. Later, he perhaps admits his recent insanity, but claims that he is now well, and that he should be discharged. In vain would be the warning that his brain is still perilously weak and irritable.

But for the power to hold him against his will, he would prematurely plunge into the busy world, with all its excitements, and the additional trying ordeal of meeting friends and acquaintances after so painful and, to him, humiliating a separation. As it is, if spared interference from without, the wise physician detains his patient a few weeks longer. When at last discharged, he is usually grateful, though perhaps deeming the doctor over-cautious.

Let us now observe what havoc this infamous law would make in a case like that just described,—a true picture of many witnessed by the writer. Glancing about the hospital ward, he sees posted the addresses of persons whose business it is to receive complaints. He learns that the superintendent is compelled to forward his letters. He perceives at once, or as soon as his brain begins to clear, that the officers are treated as if known to be dishonorable, corrupt, abusive, and untrustworthy. He knows that any tale of outrage—which the moral obliquity so often characterizing the insane may lead him to invent for mischief or in hope of release—must pass to this committee unseen by the physician. He is visited monthly or oftener by the committee, for the purpose of discovering whether he is abused, or wrongfully committed, or unduly detained. Of course, any man chafing under confinement is likely to find or invent some matter of complaint, when so urgently invited.

This committee, appointed under the influence of such a degree of popular distrust as alone could prompt such legislation, will be certain to represent and share the public prejudice. If one member, only, share this feeling, whatever raw-head-and-bloody-bones stories reach him—and many will—are sure to become public, to the infinite distress of all who have relatives in the hospital. For he is bound under heavy penalties to investigate all matters, and would not desire, even were he able, to preserve secrecy.

Among the results of this act, then, we find the destruction of the patient's confidence and of the physician's good influence and authority. The curative power of the hospital is ended. Even were it not wholly destroyed, the convalescent would be discharged half cured, by, or from fear of, the committee. The superintendent cannot attempt to enforce discipline on sane or insane, lest he be complained of and slandered.

Constant publication of tales of atrocities will lead to the removal of old cases, and prevent the sending of acute cases so long as they can possibly be retained at home. When at last intolerable in the family, they will have become incurable anywhere. The terrible distress of relatives hearing these stories, we have before mentioned.

Good attendants will refuse to remain, in peril of criminal conviction by the inventions or delusions of the insane. A lower class, reckless and unfaithful, with nothing to lose, will succeed them. Discipline, order, and tranquillity will be banished from the wards.

Worthy, efficient, and experienced men will not long consent to act as physicians in State hospitals where this law shall be placed and retained on the statute-book. Unprincipled adventurers, or at best men wholly ignorant of their duties, will succeed the educated and honorable superintendents.

In short, total demoralization must ensue in all departments of a hospital long managed under this law.

Testimony from the superintendent of the Iowa hospital, only a month after the passage of the act, shows evil effect on patients, resignation of "eight of my most experienced and valuable attendants," premature removal of four curable patients, due to deceptive letters sent out, as the first fruits of this "tree of bitterness."

To one acquainted with the history of the Iowa State hospital, the passage, in that State, of such an act seemed almost incredible. Dr. Ranney has been at the head of the hospital some seven years. He has enjoyed, to a degree unusual in State hospitals, the confidence of trustees and the legislature. His remarkable success, both as a medical and an administrative officer, including the planning and executing of important improvements, caused his representations to be treated with much respect. His friends were proud of the consideration with which his views were listened to, and the liberality with which appropriations were granted by the legislature. It is not alleged that he has done anything to forfeit this respect and confidence. Yet the General Assembly passed this act with only two or three dissenting voices,—all in the upper house! The lever exerting such energy was systematic, industrious misrepresentation; the fulcrum, popular credulity; and the power, a woman's tongue!

This woman was insane a number of years ago, and was for several months a patient in a New England hospital before her marriage. She was discharged as recovered. Twenty years later she was an inmate of the Illinois State hospital, for, we believe, two or three years. She was discharged against her will, and removed by force, as incurable, to make room for more hopeful cases, some nine years ago. She professed to suffer and to witness great abuses in the hospital, and succeeded in bring-

ing about a legislative investigation. This occupied a long time, received the testimony of many witnesses, sane and insane, did great injury to the usefulness of the hospital, and led to the resignation of its superintendent. For some reason the lady retained a bitter spite against insane hospitals, and has begun a crusade against the entire class. She is very shrewd and plausible, gaining full belief not only from those whose faith covets the impossible for its exercise, but also, in many instances, from persons of culture and intelligence. In regard to this Iowa law, we learn that she devoted herself to the task of interviewing every member of the legislature, assuring them of the existence of abuses in their own hospital, and urging the passage of this bill, which is said to be of her own concoction. Her marvellous success is shown by the unanimity with which the monstrosity was passed. Surely woman needs not the ballot, when without it she can wield, for evil the power of this lady, and for good, that of Miss D. L. Dix.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY, JANUARY 23, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. CHARLES H. THOMAS presented the following specimens:

1. *Ulceration of the colon, with a much enlarged fatty liver*, removed from a man aged 40, apparently previously healthy, who sent for him November 10, 1872, suffering from what he described as a troublesome "diarrhœa." There was no fever, and little or no abdominal pain, but some tenesmus, for which an opium suppository was ordered. Two days later, though no worse in respect to the discharges, which were now slightly bloody and mucous, he became much depressed in spirits, complaining of nausea and a distressing thirst. He had a weak, compressible pulse. From this time to his death, which occurred on the ninth day after the attack, he gradually failed in strength, seeming to die of inanition rather than of active disease.

Post-mortem examination, aided by a student, Mr. Theron Wales, revealed but a slight amount of the inflammation characteristic of dysentery in the rectum, colon, and lower portion of the ileum, as the specimens show. But nothing in the condition of the intestinal tract indicated sufficient disease to cause death. The liver, however, was enlarged to twice its normal size, much softened, and in an advanced stage of fatty degeneration. The case appeared to Dr. Thomas clearly one of mild *dysentery*, superposed upon the grave liver-affection, to which—though previously unsuspected—the fatal termination was chiefly due. The doctor afterwards learned that the patient had for years thought his liver diseased, and that morning-nausea of the most distressing character had long disturbed him. His attendance and observation of the case were seriously embarrassed by a lapse of three days after the fifth day,—during which time a "homœopath" made ineffectual trial of his potencies. When called upon to resume charge, the patient was already moribund.

2. *Encephaloid tumors of leg and liver*, removed from Mrs. ——, æt. 45, who attended as an out-door patient at the surgical clinic of the Woman's Hospital during his service there, in August, 1872, to seek relief from a bleeding encephaloid tumor, about two inches in diameter at its base, situated upon the calf of the left leg, and of six months' standing. Under applications of chromic acid, in substance, to the morbid mass, it sloughed off in about three weeks. The succeeding ulcer refused to heal completely.

Early in November the patient again consulted him in regard to a small growth at the site of the ulcer, like the one removed, which gave her some uneasiness of mind; and, further, to obtain ease from "a terrible pain at the pit of the stomach," and, to his surprise, —considering her age and her very decrepit and cachectic appearance,—to engage attendance in her approaching confinement, which was to take place three months later. This was her *seventeenth* pregnancy,—nine of her children being now alive.

By palpation, a large mass was felt in the right hypochondrium, which was exquisitely tender upon pressure. The area of percussion-dulness also was enlarged. The pain in the part had been severe and almost constant for *two years*. Nausea, which nothing allayed, except for a short time, was a source of much annoyance and consequent exhaustion. A combination of morph. sulph. and potass. bromid. in full doses gave her considerable relief from pain.

At this time cancer—of the liver primarily, of the leg secondarily—was diagnosticated. After a month she became decidedly worse, with augmented epigastric pain and irritability of the stomach, accompanied with much emaciation and almost total sleeplessness. Early on the morning of December 24, the doctor was called to her bedside, and was informed that during the night her right foot "had mortified, and that she was in agony from it." On inspection, this proved true; the sphacelation extending, within the succeeding four hours, as high as the knee. At this time her mental faculties were unimpaired, while her complaints of the pain in the foot and region of the liver were pitiful to hear. No signs of the beginning of labor were to be seen,—the pain being singularly unremitting, and always distinctly localized as above stated. But, as she was now evidently sinking rapidly, the probable near approach of death was announced to her friends, when he was told by an attendant that "something was passing from her." It was then discovered that a dead and decomposing fœtus, of the eighth month, was partially extruded from the vagina. This was removed, and an examination made, which showed that, with the placenta still within the uterus, and the latter contracted with moderate firmness, no hemorrhage was occurring; and, as she was undoubtedly *in articulo mortis*, she was not further disturbed. At this juncture Dr. Lewis D. Harlow saw her; no further action was considered advisable, and the patient died in about two hours afterwards.

Autopsy, Mr. Theron Wales assisting.—1. The accompanying growth was removed from the leg. 2. The abdominal viscera were found free from disease, excepting the liver, which weighed about ten pounds, and was studded with a profusion of encephaloid nodules like the specimen presented, and partially disorganized. 3. The uterus was found completely contracted; the placenta lying loose in the vagina; the walls of the uterus being nearly two inches in thickness, anteroposteriorly.

The specimen was referred to the Committee on Morbid Growths, who reported that the *primary* growth exhibited by Dr. C. H. Thomas was a *medullary carci-*

noma with well-marked alveolar arrangement of epithelial-like cells. The secondary growths were not examined, on account of their defective preservation.

Dr. THOMAS also called attention to what he deemed a most convenient means of transporting specimens from the place of post-mortem examination or under any circumstances where it was desirable to avoid attracting attention. This article was the simple *toilet sponge-bag* for travellers, sold by most apothecaries. This is impervious to liquids and odors; and by means of it he was able to bring specimens this evening which he could not otherwise have obtained.

Syphilitic Panaris in an Infant.—Dr. JOHN ASHHURST, Jr., mentioned that among the out-patients attending at the Children's Hospital was a child, only twenty months of age, which presented a marked example of the affection known as syphilitic panaris, or, as it is now called, dactylitis syphilitica. The patient was unquestionably a victim of hereditary syphilis, and the lesion of the finger had begun to manifest itself five months before the child was brought to the hospital,—at the early age, therefore, of fifteen months. While Dr. Ashhurst thought that syphilitic panaris was hardly so rare a lesion as it has been considered by Dr. Taylor, of New York, he looked upon its occurrence at the age of the patient whose case he was describing as somewhat exceptional.

REVIEWS AND BOOK NOTICES.

DISEASES OF THE OVARIES: THEIR DIAGNOSIS AND TREATMENT. By T. SPENCER WELLS. Pp. 478. New York, D. Appleton & Co., 1873.

Like the fire of the prytaneum, the lamp of knowledge never goes out; some hierophant stands ever ready to feed the sacred flame. Within a few short weeks, twice has this been done in a single department of science, and that by our own countrymen. This time it is by a citizen of no mean city, himself the *pontifex maximus*.

Above its fellows will the book before us be welcomed, not only by specialists, but by all those members of the profession who strive to keep abreast of the times. An author who has had an experience in ovariotomy larger than any other that ever has been or ever will be,—an experience of five hundred completed operations, twenty-eight uncompleted ones, and twenty-four cases of exploratory incisions; an experience whose record alone needs the respectable library of over thirty portly blank-books,—such an author is entitled to take rank over all others in his chosen branch of the profession. Yet the most renowned operator is not always the best teacher, and this book has somewhat disappointed us. Narrowed down to the record of one man's work, it has the "backbone of individuality," but not the scope of a complete treatise. In that sense it cannot for a moment compare with the peerless monument of industry that Dr. Peaslee has given us.

The first 116 pages describe the histology and regional anatomy of the female reproductive organs, together with the pathology of the ovaries. The diagnosis of ovarian tumors takes up the next 141 pages. The remainder of the book discusses their treatment. An intimate acquaintance with foreign literature,—so rare in an Englishman,—a sure-footed and far-sighted judgment, a conscientious industry, and the unrivalled affluence of his experience, render this treatise a noble store-house of knowledge. Yet it is not wholly invulnerable: it was the heel of the great Achilles that missed the baptism of the Styx; it is mainly the manner, and not the matter, that challenges our criticism.

To the microscopic characteristics of the ovarian fluid the author attaches but little importance. For all practical purposes, indeed, his "conclusions from micro-chemical examinations" are very impotent conclusions. Despite the alleged discovery by Waldeyer of a special epithelial tunic, he gives the ovary the usual peritoneal investment. This he contends is, after the age of thirty, the normal anatomy of that organ. In the very young, something like a germinal epithelium may be seen; but confirmatory investigations by other histologists must be made before views can be accepted which "would materially affect some physiological doctrines." He maintains that "from the sixth to the ninth month, most clearly about the eighth, the fœtus may be made to ballot upon the finger in the vagina." Now, apart from our very decided objection to the introduction of the "ballot" into obstetrics, we take exception to this teaching. The best writers upon obstetrics make the range of ballottement lie, as a rule, between the end of the third and the beginning of the seventh month; and this our own experience confirms. Were this not so, there would be no trustworthy method of diagnosticating the condition of pregnancy earlier than that by auscultation.

In the matter of anæsthetics, Mr. Wells uses the bichloride of methyl, because it contains one equivalent less of chlorine than chloroform, and is not so liable to be followed by vomiting. He gives it in the form of a spray.

Through a strange oversight, he makes no mention of Dr. Miner's treatment of the pedicle by enucleation. Of the extra-peritoneal method, however, there exists no warmer partisan. Of course the thorny question of *post aut propter hoc* at once comes up; but, after so rare a success with the clamp as a mortality of only 25.4 per cent., he could not speak otherwise. In advocating its use he offers the following excellent reasons. Owing to the very uniform presence of the Fallopian tube in the stump, in one-third of those cases in which the pedicle is treated outside of the body, the wound, for some time after the operation, reopens at every month to permit the escape of menstrual fluid. Such being the case, it stands to reason that the same phenomenon must as well take place in a stump returned into the cavity of the abdomen, exposing the woman, therefore, to all the dangers arising from hæmatocele. Then, again, whenever the pedicle is treated by the intra-peritoneal method, the raw surface of the stump becomes sealed by contracting adhesions with the intestines. A fatal occlusion of the bowel is thus liable to happen, or a collection of pus, becoming circumscribed, has ultimately to find an outlet by a long sinus.

The etiology of diseases depends almost exclusively upon statistical inquiries; but, very unfortunately, the author's have not been handled with that care which the importance of the subject demands. His facts have not been teased apart. His tables seem to have been constructed solely with a view to discover the elements of success and to authenticate his cases. Much more than this should have been aimed at. For instance, "the conjugal condition" of his five hundred patients is lamely exhibited by the bare statement that two hundred and seventy-nine were married, and two hundred and twenty-one unmarried. We are not told whether the unmarried were so *de jure* or *de facto;* what proportion of the married were widows; whether his married patients were, before the operation, sterile, fruitful, or fecund; and, in so many words, what was the average age of his patients. On these questions hinges much of importance in the elucidation of vital statistics. Verjuice and virginity, crabbedness and celibacy, are popularly deemed inseparables. Fibroid tumors, polypi and cancers, and a host of other uterine disorders, have hitherto been loosely attributed to a life of single bless-

edness. Very recently this has been made the subject of scientific inquiry. From a careful examination of the Registrar's tables, Bergeron has lately shown that marriage prolongs life in both sexes, by giving a comparative immunity from sexual diseases. This statement Mr. Wells's statistics will be found to confirm, provided the reader takes the trouble to do what the author should have done. By carefully going over these tables, we have counted up nineteen widows. Now, by deducting this number from that of the married, and by adding it to the sum of the unmarried, we obtain the enormous ratio of two hundred and forty women without husbands to two hundred and sixty with husbands. The significance of these figures can hardly be over-estimated; for it goes to show that unless the cycle of reproduction is completed in woman, she is plainly violating some great law of her being. With a population fully equal to that of the British Isles, we have in our own country certainly fewer cases of ovarian disease. May not this comparative immunity be owing to the fact that the disproportion of the sexes is less in the United States than in the mother-country?

It is gratifying to learn that the removal of one ovary does not unsex a woman. Of thirty-five of Mr. Wells's patients who got married after the operation, fourteen have since had one or more children; two have had twins. Of two hundred and fifty-nine women who were married at the time of the operation, and who have since kept him supplied with annual slips from their family Bibles, twenty-three have had one or more children. Even as regards the twenty-five women from whom both ovaries were removed, the author "has not been able to trace any peculiarity in their subsequent condition . . . as compared with those from whom only one ovary was removed, except that in only one case has there been anything like menstruation after recovery." In a professional point of view, however, a music-teacher was much the gainer by the double operation. "My voice is stronger," she writes: "I can sing the upper notes with greater facility than formerly. I can sing from A up to C natural." To those *prime donne* who wish to warble nimbly in the upper register, we gratuitously throw out this hint. The time may yet be when the capricious Opera shall impose upon its priestesses that sacrifice which a cruel dilettanteism exacted from pontifical sopranists; when, by the aid of the minor incision and the clamp, the madrigals of Pergolesi and the canzonets of the old composers shall be sung in their original key.

In order to establish the claim "that ovariotomy originated with British surgery, on British ground," much is made of a certain Dr. Robert Houstoun, who, in 1701, opened a woman's belly to the extent of two inches with "an imposthume lancet," and, with a "strong fir-splinter" wrapped with "some loose lint about the end of it," drew out some hydatids, and "about two yards in length of a substance thicker than any jelly." On another page, it is true, the author very grudgingly admits that "no one can dispute the validity of the direct claims of McDowell as designedly the first rational ovariotomist." But the edge of this compliment is blunted by a most unhappy-looking portrait of the "first rational ovariotomist," and by the saving clause that, "at the same time, it must be maintained that the still greater merit of pointing out the absence of any physiological reasons against the operation, the possibility of its safe performance in the human female, and the class of cases in which it ought to be admissible, is due to a series of eminent British surgeons."

One grave fault lowers the standard of this book; and that is an offensive egotism. The hilarity of success is too boisterous. The author's pats and others' slaps upon his shoulder are too audible and too frequent to be in good taste. His reviewers would cheerfully have done this for him, but he has been beforehand with them there; he has done it himself. Perhaps this, however, is the last British fashion; for we are told by the London *Times* that, with reference to his last novel, the late Lord Lytton "had himself expressed the very highest opinion of its merits."

By the lack of an index the usefulness of this book is much hampered; and this is not the only mark of haste. The style is by no means elegant, and not always grammatical. It is, further, too often dashed with trite scraps of Latin, and too often marred by mawkish attempts at humor and at fine writing. Skylarking with one's mother-tongue is permissible in a boarding-school girl; unpardonable in one of the princes of science. Not in motley, but in robes of purple should royalty be clad. Out of many examples of these failings we select the following: "British experience is echoed from the Continent. Neither climatic influences nor constitutional peculiarities seem to assist the physician in his efforts at cure. One might expect something different from the impetuous science of the South, acting upon the warm-blooded victims of ovarian disease, in a climate whose morbific and curative alternations are almost phantasmagoric, or from the persistent therapeutical batteries and sieges of the North, opposed to the passive resistance of phlegmatic habits. . . . The fact that vascular excitement and congestion aggravate every symptom naturally enforces in a question of matrimony the Polichinellian advice, 'Don't.'" Chapters sixth and eighth contain many choice specimens of a style which has hitherto been consecrated to the literature of table-turning and joint-cracking circles.

As a good illustration of the author's mannerism, and of the shifts that national vanity will resort to, we should like to transcribe in full a very curious argument, showing how McDowell snatched the laurel of priority from the British Lion; but, as it extends somewhat over a page, we shall merely give the thread of it. "In this country, such is the sacredness of human life, even when threatened by fatal disease, . . . that men even of the stamp of the Hunters and the Bells naturally shrank from the responsibility . . . of adopting and inaugurating it [ovariotomy] as a part of legitimate surgery; and elected rather, in the modesty of their greatness,—'*stare decisis et non quietâ movere*,'—to content themselves by tending with careful pains the last flickerings of life in their confiding patients, and soothing as best they might their prolonged sufferings, than, as it would seem to them, proceed to the choice and immolation of the sacrificial victims demanded as the inevitable price of the safety of future generations, or the aggrandizement of their own fame. And it must be remembered that . . . they [the patients] were not buoyed up, as modern women are, by the histories and promises of painless extirpations under chloroform or methylene; and that, without anything like mawkish sentimentalism, surgeons themselves had to encounter the '*peine forte et dure*' of their suppressed sympathy, and nerve themselves up to the infliction of the most deliberate and tedious eviscerative vivisection. The disease was looked upon as a mystery, and its ending in death as a matter of course; and, instead of being accompanied, as we now see it, by fretful resistance and chafings to escape, it only led—'*Deo duce, medico comitante*'—to stolid endurance or religious submission; and, on the part of the profession, to an '*ad normam*' attendance, rather ceremonial than remedial. But McDowell *was* a free man in a new country, clear from the conventional trammels of Old-World practice, *found* his patients in the most favorable conditions of animal life, *seems* to have had one of those incomprehensible runs of luck upon which a man's fate and reputation so often turn———and was happy . . . in finding suitable time, place, persons, and opportunity for testing the exercise of his Young-American

'*felix temeritas*,' based upon and guided by the Scotch '*perfervidum ingenium*' of his tutor, Bell."

Five quotations from the Latin and one from the French within the compass of a page, and the rest English on stilts! After reading this and much like it, we feel constrained to cap the above quotations by ejaculating, in a literary sense, the petition from the litany of our Anglo-Saxon forefathers,—"A furore Normanorum libera nos, Domine."

BOOKS AND PAMPHLETS RECEIVED.

Criminal Responsibility of Epileptics. By M. G. Echeverria, M.D. (Reprint from the *American Journal of Insanity*, January, 1873.) 8vo, pp. 85.

Report of the Pennsylvania Hospital for the Insane, for the Year 1872. By Thomas S. Kirkbride, M.D., Physician-in-Chief and Superintendent. 8vo, pp. 70. Philadelphia, 1873.

First Annual Report of the State Board of Health of Minnesota. January, 1873. 8vo, pp. 102.

Fifth Annual Report of the Board of Managers of the Philadelphia Orthopædic Hospital for Treatment of Bodily Deformities and Diseases of the Nervous System. Small 8vo, pp. 23. Philadelphia, 1873.

Fifth Annual Report of the Pennsylvania Society for the Prevention of Cruelty to Animals. 8vo, pp. 32. Philadelphia, 1873.

What Women Should Know. A Woman's Book about Women, containing Practical Information for Wives and Mothers. By Mrs. E. B. Duffey. Small 8vo, pp. 320. Philadelphia, J. M. Stoddart & Co., 1873.

GLEANINGS FROM OUR EXCHANGES.

Interrupted Micturition in Children (Englisch: Aertzl. Verein in Wien; from *Wiener Med. Presse*, December 1, 1872).—Excluding those cases where no urine is secreted, Dr. Englisch first spoke of cases in which the pathologico-anatomical changes interfere with the voiding of urine already secreted. This may occur from closure of the prepuce, and of the dermoid opening of the urethra,—the most usual cause,—or by a closure of the vesical opening of the urethra, of the opening of the ureter into the bladder, or the stoppage of the ureter,—a rare occurrence,—as, for example, by a foreign body.

If the urethra is closed, it is closed through a considerable portion of its length. There are frequently valves in the urethra, generally in the upper part, and there may also be valves in the neck of the bladder, and even in the ureters. They interfere with the passage of the urine only when they are broad, and present their free edge towards the bladder. The stoppage of urine by valves alters the shape of the bladder so that it may be easily detected in the cadaver. The organ becomes egg-shaped, its walls are thickened, the mucous membrane is thrown into numerous folds, and the ureters and pelvis of the kidney are widened, and nephritis and atrophy of the kidneys are present.

The voidance of the urine is rarely entirely suspended; it is generally only impeded, especially when the openings and calibre of the urinary passages are only narrowed, or when tumors are situated in them.

The narrowing may also be caused by inflammatory processes in the urethra.

Congenital phymosis may render micturition difficult, especially in those children where the foreskin has united with the glans penis, in such a way that the opening is covered by the prepuce.

In hypospadias a narrowing of the external urethral opening is generally present. If tumors are present, we shall find that the cystic and polypous forms give the most trouble; the former, though smaller, provoke the most irritation. They may be entirely new growths, or they may be the results of retention of secretions, as, for example, the dilatation of the glands of Littré in the female urethra, and the distention of the sinus pocularis in the male. Such "retention-cysts" the author found always in the median line, on the inferior wall of the urethra, at the point of junction between the pendulous portion and the bulbous, whereas in adults the lacunæ Morgagni were dilated by the retention.

Hyperplasia of the prostate gland is also a frequent cause of difficult micturition, and the author believes that a congenital hypertrophy of this gland often exists. Among pathological causes, external to the urethra, may be mentioned peri-urethritis caused by the irritative effects of coxitis upon the cellular tissue.

If concrements are in the bladder, the effects of the previously described obstructions are increased. The chief symptom is the dilatation of that part which lies behind the obstruction. If the obstruction is anterior to the fascia perinæi propria, swelling and erection accompany the voidance of the urine, and continue a little while after it is accomplished.

If the obstruction lies deeper, the fulness of the bladder becomes the cause of pain. The little sufferers cry aloud at each endeavor to pass the urine, draw up their lower extremities, and move their pelvis about restlessly. By a continued distention of the bladder, nephritis is at last produced,—the real cause of which is often overlooked in these cases by the post-mortem examiner. Catheterization should be performed with an elastic catheter. These obstructions occur less frequently in the later years of life; they usually occur immediately after birth. The bladder in children shows a marked tendency to hypertrophy.

Progressive Muscular Atrophy.—M. Hanot has recently had under observation, in the Hôpital Salpétrière, two cases of progressive muscular atrophy occurring in women affected with general palsy. One of the patients died, and M. Hanot found that the cells of the anterior columns of the cord, particularly in the cervical region, had undergone disintegration. To this well-marked and distinctly limited lesion there was conjoined diffused sclerosis of the posterior columns, which, however, was less distinctly marked, and somewhat doubtful. Hence, in addition to diffused sclerosis, described by Magnan and Westphal, there existed, in the present cases, progressive muscular atrophy, with changes in the motor elements of the spinal cord.

M. Charcot, apropos of what was said by M. Hanot, revives the question of nutritional disturbances, and the physiological interpretation that may be bestowed upon them. Samuel originated the idea of the existence of trophic nerves and endowed them with special functions, but anatomy and physiology have dealt justly with the invention, and we have now gotten rid of this new kind of nerves. What can be substituted in their place? Clinical facts are crowding together, and demand explanation. M. Charcot has taken upon himself the risk of proposing one, by throwing out a hypothesis which accords with what we know of the physiology of nerves. It is known that M. Vulpian, by joining the lingual and hypoglossal together, has proved that the motor and sensory fibres possess but one and the same function,—viz., that of transmitting the nervous current. The distinguishing point between them

is their different mode of termination in the centres and at the periphery. If, then, the nerve-fibres are capable of transmitting centripetal and centrifugal waves, it is not improbable that an excitation of the sensory fibres, propagated to the periphery, may irritate the terminal filaments with their delicate organization, described by Pacini, Meissner, Langerhans, and Biésiadecki, and cause various changes, such as zona, ulcerations, etc.

Double Luxation of the Clavicle (by Dr. Col).—The *Mouvement Médical* of November 9, 1872, contains the following report of a curious case of double luxation of the clavicle, taken from the *Gazette des Hôpitaux*. On the 29th of May, a girl seventeen years of age, while unloading a heavy dray, was jammed, by a sudden movement of the horses, between the shaft and a wall. By violent pressure on both shoulders the chest was compressed, and was at the same time rotated by the gliding of the shaft on the left shoulder, while the right was fixed against the wall.

M. Col, who saw the girl ten minutes after the occurrence of the accident, found that the left clavicle was dislocated at both of its extremities, producing a marked prominence at the acromion and at the sternum. The entire bone had been driven forwards, as it happens to the stone when a cherry is squeezed between the thumb and the index-finger.

The apparatus employed to keep the shoulder back and the ends of the bone in place consisted of a towel binding the elbow to the trunk, and three pads,—one of good size for the axilla, and two smaller ones for the extremities of the clavicle. On the 3d of July the dressing was entirely removed; the patient had some difficulty in moving her left arm, but on the 20th the movements were perfectly free, and the girl was again able to assist her father in the arduous duties of drayman.

MISCELLANY.

American Medical Association.—The twenty-fourth annual session of this body will be held in St. Louis, Mo., on May 6, 1873. Dr. T. M. Logan, of Sacramento, Cal., is the President-elect.

Physicians desiring to present papers before the Association should observe the following rule:

"Papers appropriate to the several sections, in order to secure consideration and action, must be sent to the Secretary of the appropriate section at least one month before the meeting which is to act upon them. It shall be the duty of the Secretary to whom such papers are sent, to examine them with care, and, with the advice of the Chairman of his Section, to determine the time and order of their presentation, and give due notice of the same. . . . ."

The following is a list of the Secretaries of Sections:

Chemistry and Materia Medica,—Ephraim Cutter, Boston, Mass.

Practice of Medicine and Obstetrics,—Benjamin F. Dawson, New York, N.Y.

Surgery and Anatomy,—W. F. Peck, Davenport, Iowa.

Meteorology and Epidemics,—Elisha Harris, New York, N.Y.

Medical Jurisprudence, Hygiene, and Physiology,—A. B. Arnold, Baltimore, Md.

Psychology,—John Curwen, Harrisburg, Pa.

It is proposed so to amend the By-laws that, instead of a report on Medical Education, on Medical Literature, and on Climatology and Epidemic Diseases, there shall be annually delivered before the Association, at its general meetings, an address in Medicine, an address in Surgery, and an address in Midwifery, or the Diseases of Children, the lecturers to be appointed this year by the President, afterwards by the Committee on Nominations.

Secretaries of all medical organizations are requested to forward lists of their delegates, as soon as elected, to the Permanent Secretary, W. B. Atkinson, 1400 Pine Street, Philadelphia.

Still Chartered.—*The Evening Telegraph* of March 10 contained the following item:

"Recently Judge Agnew, in the Supreme Court, gave the following decision in a case brought against the Eclectic College:

"The charter of the Eclectic Medical College of Pennsylvania was granted by act of Assembly in 1850, before the amendment of the Constitution in 1857. It contains no power of repeal. That such a charter is a contract between the State and the corporators, as to the franchises granted, is well settled: Iron City Bank *vs.* City of Pittsburg, 1 Wright, 340. Without a judicial proceeding to declare a forfeiture of the charter upon cause shown, there is no power to repeal it summarily: Erie and North East Railroad Company *vs.* Casey, 2 Casey, 301; same *vs.* same, 1 Grant, 271; Com. *vs.* Pittsburg and Connellsville Railroad Company, 8 P. F. Smith, 46–7. The act of 22d March, 1872, is the act of but one party to the contract, without a power reserved in the contract to authorize the State to do the act, and, being without the consent of the other party (the corporators), is nugatory, because of the Constitution of the United States, article 1, section 10, and the Constitution of the State, article 9, section 10, forbidding the passage of laws impairing the obligation of contracts. The recital in the preamble of the act of 1872, that it had been ascertained, by evidence produced before a committee of the Senate, that the Eclectic Medical College had been guilty of unlawful, discreditable, and dangerous acts, on which the repeal was thereupon declared, does not help the case. The committee had no judicial power, and could not turn itself into a court of justice to take jurisdiction, summons and try the corporation for its alleged offences. It was but a portion of the legislative body itself, charged with a function merely auxiliary to legislation. Its judgment was no more than the judgment of the body conferring upon it the power of inquiry. The act of 1872, repealing the charter, was therefore without legislative force, and void. The corporation is entitled to a trial in due course of law, to ascertain its breach of duty, before its charter can be taken away. A franchise is a valuable privilege, and is property in the contemplation of law; and the body possessing it is as much entitled to a judicial determi-

nation of its right, or want of right, to hold it, as a natural person is of his right to his lands or his goods. The defendant is therefore entitled to judgment upon his demurrer.

"Demurrer sustained, and judgment thereupon for the defendant, that he go without day, and be paid his costs."

THE lectures in the schools of medicine and pharmacy at Montpellier, in France, suspended recently by government on account of certain irregularities on the part of some of the students, were resumed on the 14th of February; only those pupils being admitted, however, who were provided with tickets by the authorities. No clear statement of the exact cause of the trouble has as yet been made public.

SUICIDE.—On the morning of March 5, Dr. Alfred E. Walker, a promising young physician of New Haven, Connecticut, shot himself dead in his room at the New Haven Hotel. The act resulted from chronic melancholy, almost amounting to insanity, under which he had for some time been suffering.

CORRECTION.—Our recent announcement of a new edition of the "United States Dispensatory" was premature, as the work of revision is one of great labor, requiring much time for its performance. We should have stated that the material for the revised edition was being collected.

ACCORDING to the "Philadelphia Medical Register," lately issued, there are six hundred and ninety-nine regular physicians in the city. About fifty of these have retired from active practice.

APPOINTMENT.—Dr. A. W. Mathews, of Media, has been appointed by Governor Hartranft quarantine physician to the port of Philadelphia, to succeed Dr. John L. Gihon, removed.

DR. SOCRATES N. SHERMAN, a leading physician and public man of Ogdensburg, New York, died early in February, at the age of 71.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending March 8, 1873, were 332; 169 adults, and 163 minors. 7 were of bodies brought from the country; making the mortality of the city 325. Among the assigned causes of death were:

Consumption of the Lungs	43
Other Diseases of the Respiratory Organs	46
Diseases of the Circulatory Apparatus	12
Diseases of the Brain and Nervous System	54
Diseases of the Digestive Apparatus	23
Zymotic Diseases (12 from Scarlet Fever, 1 from Small-pox)	36
Typhoid Fever	5
Casualties	6
Cancer	5
Diseases of the Urinary Organs	7
Pyæmia	2
Rheumatism	2
Tumors	2
Debility (including "Inanition" and "Marasmus")	37
Still-born	20
Old Age	15

(The interments reported for the week ending March 9, 1872, were 443.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

		THERMOMETER.		BAROMETER.
		Max.	Min.	(2 P.M.)
Mar.	2	42.0°	27.5°	30.17 in. (Snow.)
"	3	37.0	17.0	29.83 in. (Snow.)
"	4	24.0	8.0	30.33 in.
"	5	25.0	10.0	30.70 in.
"	6	33.0	15.0	30.77 in.
"	7	44.0	23.5	30.51 in.
"	8	47.0	32.5	29.99 in.

The mean temperature of the month of February was 30.57°.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 25, 1873, TO MARCH 10, 1873, INCLUSIVE.

VOLLUM, E. P., ASSISTANT-SURGEON.—The leave of absence granted by S. O. 25, Department of the Platte, February 15, 1873, extended thirty days. S. O. 22, Military Division of the Missouri, February 24, 1873.

POPE, B. F., ASSISTANT-SURGEON.—To accompany 7th Regiment of Cavalry to Fort Randall, Dakota Territory, and, after completion of this duty, return to Louisville, Kentucky, reporting to Medical Director, Department of the South. S. O. 40, Department of the South, February 26, 1873.

CAMPBELL, JOHN, SURGEON.—Granted leave of absence for thirty days. S. O. 41, Department of the East, March 3, 1873.

MACKIN, CHARLES, ASSISTANT-SURGEON.—Assigned to duty at Yorkville, South Carolina. S. O. 45, Department of the South, March 4, 1873.

NAVY NEWS.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY, FROM FEBRUARY 1, 1873.

Medical Director W. S. W. RUSCHENBERGER,—Waiting orders.

Medical Director J. M. FOLTZ,—To Naval Hospital, Philadelphia.

Medical Director WILLIAM MAXWELL WOOD,—As Inspector-General of Hospitals and Fleets.

Surgeon HENRY C. NELSON,—As Recorder of Naval Medical Board.

Medical Inspector SAMUEL F. COWES,—To Navy Yard, Portsmouth, New Hampshire.

Medical Inspector ALBERT L. GIHON,—To special duty, Bureau of Medicine and Surgery.

Medical Inspector EDWARD SHIPPEN,—Waiting orders.

P. A. Surgeon HENRY STEWART,—Naval Station, New Orleans.

Surgeon F. E. POTTER,—Receiving Ship, Portsmouth, New Hampshire.

Surgeon SOMERSET ROBINSON,—League Island Navy Yard.

P. A. Surgeon H. M. RUNDLETT,—To Iron-clad "Terror."

Surgeon J. H. CLARK,—Waiting orders.

Assistant-Surgeon S. W. LATTA,—Waiting orders.

Surgeon A. A. HOEHLING,—Sick leave.

Surgeon THOMAS C. WALTON,—To U.S.S. "Juniata."

Assistant-Surgeon H. C. ECKSTEIN,—Ordered home.

Assistant-Surgeon EDWARD EVERS,—To U.S.S. "Narragansett."

Surgeon B. F. GIBBS,—To U.S.S. "Richmond."

Assistant-Surgeon E. C. THATCHER,—Resigned.

Medical Inspector ALBERT L. GIHON,—To European Station, as Surgeon of the Fleet, on June 1.

SATURDAY, MARCH 22, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

(Continued from page 371.)

LECTURE V.

CHRONIC LARYNGITIS.

CHRONIC inflammation of the larynx is a frequent attendant upon chronic pulmonary phthisis; is one of the later manifestations of syphilis; is an accompaniment of carcinomatous disease; and is often a sequel to acute laryngitis. The inhalation of minute particles of foreign bodies suspended in the air is a very frequent cause of chronic laryngitis.

In most cases, the trachea participates more or less extensively in the inflammation; and in some there is at the same time an inflammatory condition of the naso-pharyngeal mucous membranes, which is sometimes antecedent to the laryngeal affection, and sometimes subsequent to it.

Chronic laryngitis is very apt to terminate in ulceration of the mucous membrane, giving rise to the condition designated as ulcerative chronic laryngitis.

Upon laryngoscopic inspection the mucous coverings of the parts involved will always be found more or less congested, their color varying from a mere deepening of the normal pink or red, to a deep-red or even purplish-red. Enlarged veins are often seen coursing beneath the surface of the epiglottis and the ary-epiglottic folds, and occasionally on the vocal cords. The mucous membrane is generally thickened and indurated, and frequently has a velvety appearance. The vocal cords do not always participate in the general condition, their color often seeming whiter than natural by contrast; but they are very apt to be thickened at their edges, even when not much changed in color. They are usually involved, however, and then they have a red or yellowish color, and their surface is rough and uneven. Frequently masses of glairy mucus are seen adhering to them, stretching often in viscid strands from one side to the other. Deposits of mucus are very apt to be seen upon the inter-arytænoidal fold of membrane at the base of the cartilages of Santorini, and must not be mistaken for ulcers.

The epiglottis is frequently thickened, sometimes to four or five times its normal dimensions, with more or less alteration in its shape, and loss of symmetry, so that it has a nodulated and spongy appearance. The epiglottis is very apt to have some erosions upon its edge, even when no similar appearances can be seen elsewhere. In severe cases, however, the mucous membrane is usually ulcerated in several localities; most frequently upon the posterior laryngeal wall, the ary-epiglottic folds, and upon the posterior portion of the vocal cords; and irregular papillary excrescences often mark the site of these ulcerations.

Syphilitic ulceration cannot be said to have any specific appearances distinguishing it from that occurring in tuberculosis. The edges of the syphilitic ulcers are perhaps more frequently sharper in outline, the surrounding tissue redder in color, and the superficies of the ulcer less regular in appearance. When the trachea is involved, the membrane covering its rings is reddened, and the color of the intervening spaces deepened into a darker red. Ulceration in the trachea can sometimes be detected with the laryngoscope, but, seen as it is in perspective, it furnishes only a vague idea of the extent to which this ulceration may have progressed; the post-mortem examination frequently revealing a much greater amount of destruction than the laryngoscopic appearances would have led us to suspect during life. The laryngeal ulcers are sometimes of considerable extent, and are usually covered with a grayish- or ash-colored pus; when situated near the points of articulation of the cartilages with each other, they are usually associated with perichondritis and necrosis of the underlying cartilages. In tuberculous cases the ulcerations heal very tardily, and often reappear in the same or in other localities. The syphilitic ulcer, when once cicatrized, usually remains healed. Ulceration, independent of any constitutional taint, is cured readily and permanently, as a rule, under appropriate treatment.

Sometimes the pyramidal sinuses and the valleculæ between the tongue and the epiglottis also participate actively in the diseased condition, and are seen to be inflamed, and at times even ulcerated. Ulcers in these situations are generally more readily amenable to treatment than the intra-laryngeal ulcerations. In the course of the disease, the pharynx, palate, and adjacent structures are apt to become involved, if they have not been affected early in the complaint; and the ulcerations here assume a character similar to that within the larynx.

Chronic laryngitis occasionally produces a condition known as stenosis of the larynx, either by extensive deposits of the products of inflammation in the sub-mucous laryngeal tissues, or as a result of the contraction of the cicatricial tissue which is formed upon the healing of ulcers. This stenosis or diminution of the calibre of the tube is most frequently met with beneath the glottis, but it may be seated in the glottis itself, and also in the upper portions of the larynx; and it almost always ensues when there has been any extended destruction of the cartilaginous framework of the larynx.

The symptoms of chronic laryngitis, at first, do not present any characteristic phenomena, and are generally altogether inadequate to explain the amount of disease present, even in cases where there

is ulceration of the vocal cords; unless there is extensive ulceration of the epiglottis giving rise to dysphagia. The disease is generally attended by hoarseness of the voice, and a sense of tickling or dryness in the upper part of the throat, which gives occasion to a short, dry, hacking cough. Often it is attended with a feeling of uneasiness or positive pain in the larynx; and soreness to a greater or less degree will be felt, if the wings of the thyroid cartilage are compressed, or if the larynx is pushed back against the vertebral column. If the disease is permitted to go unchecked, these symptoms gradually become more and more distressing; the voice ultimately becomes extinguished; the cough grows more troublesome, painful, and of longer continuance, the paroxysms, towards the last, bathing the patient with sweat, and producing great debility; the expectoration is more copious, and, in ulcerated cases, streaked with blood; the pulse rises often to 120 beats in the minute; hectic and emaciation indicate the approaching dissolution. The dysphagia becomes intense as the ulceration of the epiglottis and of the ary-epiglottic folds increases in extent, so that in many cases deglutition is finally impossible, usually first as regards fluids, and later with solids also. Food swallowed is painfully regurgitated, and the thirst cannot be allayed, so that the patient often perishes from actual starvation. When the epiglottis is deeply ulcerated at the sides, a pain often extends into the ears, so great at times that the patient complains much more of the pain in the ears than of that in the larynx; and this pain is increased by swallowing, or by local applications, and is caused by irritation of the auricular branch of the pneumogastric nerve, probably from the extension of the inflammatory and ulcerative processes outwards towards the pharyngeal tissues in its neighborhood.

Hoarseness is sometimes present to a marked degree, when there is very little evidence of disease in the cords themselves. It is then probable that a paralysis has occurred, either from local irritation of the terminal filaments of the nerves of the larynx, or from interstitial inflammation between the fibres of the laryngeal muscles. Thickening of the vocal cords by interstitial inflammation, and not from vascular turgescence merely, always produces hoarseness; and their destruction by ulceration entails aphonia. On the other hand, the vocal cords may be deeply congested without producing marked hoarseness; and moderate hoarseness only may ensue even upon extensive ulceration of the tissues of the cords. The character of the voice, therefore, is no certain index of the condition of the vocal cords, a point which can be ascertained only upon laryngoscopic inspection.

Many cases of chronic laryngitis appear to occur without being preceded by the acute disease in any of its forms. The patient is in comparatively good health; and, without exposure to cold, or any other accountable cause, gradually recognizes that there is some slight trouble in his throat. There is an occasional and often momentary huskiness of the voice in speaking; an occasional expectoration of a small pellet of viscid mucus, with a sense of dryness in the throat; at times a feeling of impediment to respiration at night, the patient awakening with a sense of suffocation, a sensation which is usually relieved by swallowing saliva or a draught of water. These, perhaps, may be the only inconveniences that the patient experiences, until, after a while, soreness supervenes, with increased expectoration, perhaps with a partial subsidence of the feeling of dryness. In this condition, the state of chronic laryngitis having become permanent, the patient may continue for years, suffering but little with his throat, except when the symptoms have been aggravated by powerful exercise of the vocal organs, or by undue exposure.

There is a form of chronic laryngitis sometimes met with, most frequently in adults between twenty and forty years of age, which, although attributed by the patient to a severe cold, or sore throat, as the initial disturbance, seems to be due in a great measure to sumptuous living, with the abuse of condiments, and the free use of alcohol. The mucous membrane of the pharynx, palate, and palatine arches is found relaxed and puffy; the tonsils often slightly enlarged; and the uvula is generally relaxed to a slight degree. There is often no follicular pharyngitis present, but the entire membrane of the pharynx and naso-pharyngeal region is of a deeper color than is normal, and appears swollen and bulged forward from the effusion of lymph that has occurred in it. The entire larynx is always found congested, and the vocal cords have a pink or red color instead of being white. This redness of the cords is most marked at their arytænoidal insertions, so that the maculæ flavæ appear as maculæ rubræ. The mucous membrane over the cartilages of Santorini is quite red and infiltrated, and this condition may extend along the whole ary-epiglottic fold. An accumulation of very viscid mucus upon the inter-arytænoid fold gives rise to ineffectual coughing, which keeps up the congestion of the larynx. The hoarseness, in this complaint, is marked and constant; less evident often in singing than in ordinary conversation; more marked early in the morning, and after a meal. There is usually a feeling of fulness in the throat, with a consciousness of the presence of phlegm. There is no pain, but a constant uncomfortable annoying sensation in the throat. The expectoration is slight, and the sputa are usually quite firm and of a yellowish color.

In other cases the expectoration is much more profuse, interfering with sleep; and there may be more or less derangement of nervous and gastric origin. This condition is very often termed a chronic catarrhal laryngitis.

Inhalations of iodine or carbolic acid, or a combination of the two, or of the muriate of ammonia, have proved a most efficient mode of treatment for these conditions. The diet must often be restricted, condiments avoided, and stimulants interdicted; and the general health improved by appropriate alterative and tonic treatment. The local treatment, when required, does not differ from that to be recommended for chronic laryngitis in general.

THE CHRONIC LARYNGITIS OF PHTHISIS.

The lecturer does not believe in the existence of any distinct disease to be called "laryngeal phthisis," whether it be destructive ulceration of the laryngeal mucous membrane so often observed even in the early stages of general phthisis, or whether it be the extensive chondritis or perichondritis of the older authors. He is inclined to think it altogether doubtful if ever a case existed in which the tuberculous disease was confined to the laryngeal structures. Simple chronic laryngitis, catarrhal or ulcerative, is often a curable affection; but its occasional resistance to treatment, or persistence in spite of it,—proceeding gradually from bad to worse until it produces a characteristic group of subjective symptoms,—cough, dyspnœa, purulent expectoration, and finally diarrhœa and hectic,—has led many to the opinion that there exists a special disease in which tubercle is limited to the larynx.

It is still a mooted question among pathologists whether an eruption of real miliary tubercle ever takes place in the lining membrane of the larynx. Rindfleisch* admits the possibility of such an occurrence, but states that the miliary tubercles are so few, and can be so rarely detected, that they must be regarded as a very insignificant factor in the production of the ulcerative process of "laryngeal phthisis." The enlarged mucous glands of the laryngo-tracheal mucous membrane, which have been hyperplastically distended with retained secretions by the long-continued catarrhal inflammation present in all these cases, must be considered as a non-tuberculous element. The presence of these inflammatory products in the glands speedily leads to their ulcerative destruction; and, by the confluence of several of these ulcers, we have that racemose form produced so generally considered as characteristic of the "tuberculous" ulcer.

In opposition to these views are the statements of several recent observers, familiar with the use of the laryngoscope, who claim to have detected tubercles deposited in the mucous membrane of the larynx early in the disease; and we find Gibb† and Marcet‡ actually depicting them in their illustrations of the laryngeal image. From the preceding explanation, there can be scarcely any doubt that the nodules, so large and numerous as to be plainly visible to the unaided eye, must have been enlarged mucous follicles. The lecturer stated that he had frequently observed, however, in tuberculous patients, groups of enlarged glands over the arytænoid cartilages, the corpuscles of Santorini, and upon the lateral walls of the larynx, which presented somewhat the appearance described and depicted by the authors in question; but that he never had had reason to believe them to be tubercles, but had held them to be prominent glands, to the external coloration of which a yellowish tinge had been given by the tension of the mucous membrane over them. A similar appearance is often found in some simple inflammations occupying the inside of the lips and the cheeks.

Some cases of pulmonary phthisis are subject to intercurrent attacks of ordinary catarrhal laryngitis, the latter being wholly unconnected with tuberculization. Cases of chronic laryngitis of this nature are amenable to the same treatment as chronic laryngitis unassociated with tubercle; and they are carefully to be differentiated from tuberculous laryngitis, on the score of efficient prognosis and the liability of crediting therapeutic remedies with capabilities which they do not possess.

(To be continued.)

ORIGINAL COMMUNICATIONS.

FOUR COMPLICATED LABORS.

BY HORACE WILLIAMS, M.D.

PLACENTA PRÆVIA—FORCEPS.

MRS. F., in the last month of her fourth pregnancy, sent for me one morning, having lost considerable blood per vaginam through the night. I found her pale and languid, but up and about,—the hemorrhage having ceased; but, her three previous pregnancies having been entirely normal, I made an examination. There were no pains, nor signs of labor. A half-inch of cervix remained, and the finger, readily entering the relaxed os, encountered something intervening between it and the presenting part of the child, which, from consistence and feel, gave little doubt of the existence of a placental presentation. In the absence of hemorrhage and all signs of labor, the horizontal position, with gallic acid and acid. sulph. aromat. internally, was directed. The next morning a similar loss of blood occurred, but had ceased on my arrival, and the absence of pains again suggested non-interference. Beef-tea, milk-punch, and absolute quiet were enjoined. The next morning a hurried message summoned me to Mrs. F., whom I found in a state of syncope, from a most alarming hemorrhage, still in progress. Immediately passing my hand into the vagina, it was discovered that labor was inaugurated, the cervix taken up, and the os, commencing to dilate, seemed entirely covered by the placenta. In the syncopal condition, relaxation of all the parts was so complete that dilatation was rapidly accomplished by the hand, with partial separation of the after-birth, and rupture of the membranes. But little liquor amnii escaped, as pressure upon the fundus and feeble uterine contractions now caused the vertex to engage in such a way as to plug the os, and by pressure on the detached segment of the placenta to check the hemorrhage. The mother's exhaustion was, however, extreme, and rapid delivery seemed called for, on her account and the child's as well. So, without further delay, I applied the forceps, and delivered her of a living child, which, while far gone, was resuscitated, and throve subse-

quently. The placenta followed without trouble, and showed its segment of detachment about the os and cervix to have been one-third of its area, and the implantation right lateral and posteriorly. Mrs. F's. lying-in was without drawback, and lactation was very free. Anæmic palpitation, tinnitus aurium, and swelling of the feet were subsequently annoying, but yielded readily to iron and quinia.

PRESENTATION OF FOREARM, WITH PROLAPSE OF CORD —VERSION BY THE HEAD, WITH REPLACEMENT— FORCEPS.

When called to Mrs. H., in labor with her first child, I found that pains had regularly recurred for several hours, increasing in strength and frequency, but had ceased with one which had ruptured the membranes, about twenty minutes before my arrival. On making an examination, I found one hand, apparently the right, and the forearm, with quite a long bunch of the cord, resting in the vagina. In the absence of pains, and the relaxed condition of the os, the hand and loop of the cord were readily replaced, and, recognizing the head of the child lying in the left iliac concavity, my hand exteriorly assisting, it was brought down to engage, where a timely pain fixed it. Not knowing how far the cord might still be under pressure, and the child likely to suffer, in the protracted delivery of a primipara, I applied the forceps, and, with as much rapidity as seemed safe to the mother, delivered her of a living child. Convalescence took place without any notable feature.

DROPSY OF THE AMNION—PREMATURE LABOR—SHOULDER PRESENTATION—VERSION BY THE FEET.

Mrs. M. sent for me in her fourth pregnancy, one month in advance of her calculated time. She stated that she had been more delicate than usual through the previous months; had had little swelling of her limbs, but that her abdomen was as large or larger than previously at full term. She had for years been troubled with a chronic prolapse of the bladder, with the anterior wall of the vagina, adding much to her discomfort at this time, and perhaps complicating the sequel. Pains had set in that morning, and at noon the os was half dilated, and a segment of abnormally thick membranes engaging, but neither per vaginam nor by abdominal palpation was I able to satisfy myself of the position of the child. There was more fluctuation than normal in the uterine tumor, and palpation gave the idea of a longer transverse than vertical diameter. The os being now dilated, with some misgivings the membranes were ruptured, when there immediately took place a flow of liquor amnii, which, deluging the bed, ran over its side in three streams, partly filling as many utensils placed for its reception. It now became apparent that the presentation was one of the right shoulder, the head resting in the left iliac concavity, the body of the child being transverse. Conceiving that version would be more safe with the use of ether, I sent for Dr. Cleemann, and, in his absence from home, for Dr. Curtin. Both subsequently arriving, we proceeded to administer ether, preparatory to version by the feet. The right hand passed to near the fundus found both feet without difficulty, but traction was first made upon the left limb in view of the right shoulder presenting. As it rose from its engagement at the os, both feet were grasped, and by strong traction brought down to the outlet, the body and shoulders following. The delivery of the head was arrested by the chin against the pubis, and probably somewhat by the engagement of the prolapsed bladder at the outlet. The delay was such that the child was resuscitated with exceeding difficulty. There was no subsequent retention of urine, and convalescence was rapid. Had not the diagnosis of the position been rendered uncertain by the excess of liquor amnii in this case, bipolar version prior to the rupture of the membranes would undoubtedly have been the preferable procedure.

PROLAPSE OF THE CORD, COMPLICATING A FOOTLING PRESENTATION.

I was called at 9.30 A.M. to Mrs. T., who had been in labor with her fifth child since 2 A.M. Examination revealed a segment of unruptured membranes protruding at the vulva, which being ruptured, a loop of the cord was found occupying the vagina, the presentation being that of both feet. The pulsations of the cord indicating that the child was suffering by pressure somewhere above, it was thought safer to hasten delivery by traction on the feet, rather than lose time in any perhaps futile efforts to replace the cord in the knee and elbow position. The lull of the pains caused by rupturing the membranes was of short duration when traction was once commenced. They became frequent and vigorous, and in less time than the recital occupies the child was delivered,—apparently, however, none too soon, as a half-hour of douching, mouth-to-mouth respiration, and the Marshall Hall method, was requisite to establish breathing.

1711 PINE STREET, March, 1873.

LARGE DOSE OF CHLORAL.

BY G. TROUP MAXWELL, M.D.,
New Castle, Delaware.

AN instance in which an enormous quantity of chloral—at least two hundred and ninety grains—was taken without apparent ill effect, occurred recently under my observation. It seems to me sufficiently interesting and instructive to merit publicity; and I therefore place the facts before the profession.

A gentleman who is laboring under a complication of diseases had been for perhaps two months taking chloral at bedtime, to procure sleep, in quantities varying from fifteen to thirty grains at a dose. Latterly he had taken thirty grains oftener than a less quantity, and that dose would frequently cause him to sleep until about noon the next day. Having remonstrated against his taking a larger dose than was required to give him sleep through the night only, he was directed to confine the dose to fifteen grains, which was to be repeated if necessary.

On the 1st of February a single dose of fifteen grains was procured, which was administered to him early in the night; but a four-ounce phial, in which seven drachms, or four hundred and twenty grains, were dissolved in syrup, was also gotten from his druggist. The phial was labelled "fifteen grains to the teaspoonful." A teaspoonful from this phial was given to him after an interval of less than two hours from the taking of the first dose. His wife, who was suffering with headache, then went to bed, and, after sleeping a while, heard her husband at the stand on which the phial was. In reply to her inquiry "if there was anything she could do for him," he said, "No; I am only taking a teaspoonful of chloral;" then, returning to bed, he quickly fell into profound sleep.

Next morning the wife discovered that her husband had taken *more than half the contents of the phial.* Not appreciating the nature of the case, and not perceiving anything unnatural in his appearance or sleep, her alarm was not excited until my visit at noon, when, if there had been danger, it had all passed; for he was then sleeping naturally and quietly, and was easily awakened, but quickly lapsed into deep sleep again. Thus he continued until about six o'clock P.M., when he became fully aroused, under the impression that he had been sleeping only three hours.

Upon a careful measurement of what remained in the phial, I found one ounce and three drachms, or about one hundred and forty-five grains. He had taken, therefore, *about two hundred and sixty grains at one time,* and in all, that night, two hundred and ninety grains! The phial was resting upon a stand which had a marble top and was surrounded by oil-cloth; and, as the solution was a thick syrup, if any had been spilled it must have been seen. A careful examination was made, and there was no evidence that any of the solution had been lost. I concluded, therefore, that the whole of it was swallowed; which is by far the largest quantity of chloral I have ever known or read of being taken by one who was not in delirium or convulsions, or not in great suffering, and would seem to indicate that the limit of its harmlessness may be much further extended than has hitherto been supposed.

[A case in which four hundred and sixty grains of chloral were taken, without fatal effects, was reported in the number of this journal for October 15, 1870, p. 23.—ED.]

MIASMATIC INFLUENCE AS A CAUSE OF SWELLED TESTICLE.

BY D. HAYES AGNEW, M.D.,
Professor of Surgery in the University of Pennsylvania.

THE influence of miasmatic causes in the production of certain inflammations sometimes appears in very unexpected directions. The two cases subjoined will serve to illustrate a manifestation quite unique to myself.

Case I.—Mr. ——, a gentleman from California, a few days after his arrival in Philadelphia, was attacked with orchitis. The most direct inquiries failed to elicit any evidence of syphilitic, gonorrhœal, or strumous origin. The pain was intense, shooting upwards along the course of the spermatic cord, and with suffering in the lumbar region. The gland became very much swollen and exquisitely sensitive.

Leeches were directed over the cord, a purge administered, anodyne lotions applied to the parts, and full doses of anodyne to allay pain and secure rest. To my astonishment, no alleviation was experienced; profuse perspiration set in towards evening, preceded by cold feet, but no distinct, well-pronounced rigor. Somewhat annoyed at the singular obstinacy of the case, I again instituted a careful inquiry into the circumstances attending his journey, and found he had been some time on the Isthmus. Catching now at the possibility of a miasmatic origin, I ordered a few large doses of quinine, when all the symptoms disappeared as if by magic.

Case II.—Mr. B., an engineer, a man of unusual physical vigor, suffered from a mild urethritis. He was directed to inject, two or three times a day, a solution of the sulphate of zinc, half a grain to the ounce of water. In a few days the right testicle became enlarged, very painful, and accompanied with rigors and febrile disturbance. Supposing the case was one of propagated urethral inflammation, leeches were ordered, and a thorough application of the nitrate of silver made over the scrotum, his bowels opened by a cathartic, etc. Several days elapsed, and still no mitigation of the symptoms. Profuse sweating next set in; and I now recalled the case related as No. 1. On inquiry, I found he had recently come up from the South, where he had been exposed to miasm, from which several of his companions had suffered. He was now ordered eighteen grains of quinine in four doses, at intervals of two hours; and before twenty-four hours the most decided change had taken place, requiring only about thirty-six hours more for the removal of all acute symptoms and the rapid resolution of the disease.

NOTES OF HOSPITAL PRACTICE.

CLINICAL NOTES.

WILLS OPHTHALMIC HOSPITAL.

SERVICE OF GEORGE C. HARLAN, M.D.

Reported by W. H. WINSLOW, M.D.

RETINITIS PIGMENTOSA.

A. H., a woman, æt. 45 years, of nervous temperament, came to the clinic in January, 1873, complaining of defective vision. Upon inquiry, no hereditary predisposition to blindness could be traced. Her father died æt. 60 years, of senile gangrene, and her mother, æt. 90 years, of old age, and could see to sew up to the time of her death without glasses. The patient had one brother living, with perfect vision, and she could not say whether or not there was any consanguinity between her parents; though she believed there was none. She said "that ten years before, one evening at dusk, she was picking cherries in a garden with a merry company, and, as she approached the tree, she struck her face against the trunk, which excited the laughter of her companions, and much annoyed her."

Shortly after this, she visited a benevolent club to pay her dues, and when the change and her card were returned she was unable to see either, although the room was brilliantly lighted with gas. Again, one even-

ing, in a chamber where the gas was burning dimly, she attempted to give a sick person a glass of water, but could see neither the patient's mouth nor face.

Her sight became gradually more imperfect as the years passed, and hemeralopia continued a prominent symptom. One evening, in bright moonlight, she ventured out, but fell into a lime-pit filled with fresh mortar, and had never been out unattended after sunset since.

After the evening twilight her vision was completely in abeyance, and was only slightly benefited by artificial light. In looking at a large object, she saw only peripheries, which was explained by her very much contracted field of vision.

Her chromopsies were frequent and remarkable; she had distinct subjective perceptions of green, purple, and red, but no color-blindness.

Vision at the maculæ luteæ was $\frac{20}{XL}$. The fields of vision were nearly alike in outline, and had, at one foot distance, vertical diameters of seven inches, and horizontal of six.

Ophthalmoscopic examination showed lenses and humors without opacities and apparently healthy; the disks had sharply-defined outlines and were slightly atrophied, and the retinal arteries were diminished in calibre, with the veins tortuous and full.

All over the fundus of each eye, except in the region of the maculæ, were scattered the reddish-brown and black, ragged, striated masses of pigmentary deposit in the retina, increasing towards the peripheries and most extensive, as usual, at the inner sides of the disks. No roundish or oval masses, but irregular, feathery outlined islands, connected by indirect linear prolongations. Many arterial branches had deposits of pigment along their walls, occasionally overlying the vessels and hiding them for a line or two.

Slowly but surely the disease had progressed, and was progressing; the field of vision contracting, and science unable, as yet, to afford relief. She was ordered glasses of $+\frac{1}{24}$ to neutralize her hypermetropia, and directed to avoid unnecessary and excessive use of her eyes, and dismissed. Upon a subsequent visit she said "that the glasses enabled her to sew and read by daylight, quite comfortably."

TWO CASES OF PARTIAL PARALYSIS OF THE THIRD PAIR OF NERVES, TREATED BY EXTRACT OF CALABAR BEAN.

W. McC., a man æt. 26 years, in average health, and a laborer by occupation, came to the hospital November 11, 1872, with the following history: Eighteen months before, he had noticed that the pupil of the left eye was larger than its fellow, and that his sight was getting dim. There had been little change up to the time when he applied for treatment.

In the right eye the sight was normal, $V=\frac{20}{XX}$ of Snellen's types, and near vision was perfect. In the left, it was only $\frac{20}{LXXX}$, but rose to $\frac{20}{XXX}$ when a hypermetropia of $\frac{1}{36}$, which the paralysis of the ciliary muscle had made manifest, was corrected by a convex glass. The eye was useless for near vision, and the pupil dilated to more than half its full extent. There was no paralysis of any other muscle supplied by the motor oculi than the constrictor of the pupil and the ciliary muscle. He stated that he had had chancres twice, in 1864 and in 1865; but, with the exception of a pharyngeal catarrh, no syphilitic history could be elicited.

He was put upon iodide of potassium and the corrosive chloride of mercury, and the pure extract of calabar bean, merely softened with glycerin, was applied to the inner surface of the lower lid.

Twenty minutes after the application, the pupil was smaller than that of the other eye, and he could read small print with ease. Not only was the hypermetropia of $\frac{1}{36}$ overcome, but a high degree of myopia was developed by the spasm of the muscle of accommodation, and he could see distant objects distinctly through a $-\frac{1}{11}$ glass.

The extract was applied three times a week, and always produced the same effects, which subsided each time in about a day.

A solution of sulphate of atropia applied to the eye made the partial dilatation complete; showing either that the paralysis of the sphincter fibres of the iris was not entire before the application, or that atropia has a stimulating effect upon the dilating fibres, which latter is maintained by some eminent authorities.

The other case, in the person of M. B., a girl æt. 11 years, was complicated by paralysis of the internal rectus. Six weeks before her appearance at the clinic she fell heavily upon her back and remained stunned for ten minutes. Severe pain in and around the left eye supervened, with diplopia and much nausea. Two weeks afterwards her mother noticed an increase in the size of the left pupil over that of the right. Upon examination the left pupil was found dilated to a mere rim, but there was no injection of the vessels, and the eyes appeared otherwise normal. Vision in the right was $\frac{20}{XX}$. In the left it was only $\frac{20}{C}$ of Snellen, but with a $+\frac{1}{36}$ glass she read $\frac{20}{XXX}$. There was no ptosis, but marked diplopia, and the internal rectus was completely paralyzed. She was ordered iodide of potassium gr. iij three times a day, and the calabar extract was applied to the inner surface of the lower lid, as in the previous case.

In about twenty minutes after the application the pupil was contracted to one-quarter the size of the other, and she read $\frac{20}{XXX}$ of Snellen with ease. The mother stated that the pupil invariably dilated again before they reached their home in Frankford; but at each visit a slight gain could be noticed.

Applications of the extract were made every other day for two weeks, when the pupil was found to be of medium size and slightly responsive to light; she had gained some power over the internal rectus, and moved the eye considerably beyond the middle line.

To test more certainly the effects of the calabar bean, the iodide was discontinued, and the extract was applied every other day. At the end of the third week the paralysis of the internal rectus was scarcely noticeable, and the diplopia existed only above the horizontal line and to the right of the median; the pupil continuing about the same. The extract applied at this time caused in twenty minutes extreme myosis and myopia of $-\frac{1}{24}$. In another week the diplopia existed only beyond about 35° to the right of the middle line, the pupil was much smaller, and a $+\frac{1}{48}$ glass made $V=\frac{20}{XXX}$. Treatment was continued.

At the end of the fifth week the pupil continued much smaller, the field of binocular vision was increased, and she read $\frac{20}{L}$ without glasses. She ceased to attend after this time, as she no longer suffered any inconvenience.

LATENT HYPERMETROPIA.

A. R., a delicate-looking woman, æt. 29 years, applied for treatment in February, 1873. She said that up to the birth of her child, a year before, her sight had been perfectly good, but that since then she had not been able to read or sew without fatigue and pain. Her health, previously good, had not been so since confinement, and she had been obliged to give up nursing her child when he was a few months old.

Hypermetropia was at once suspected, but it was found that she could read number XX at twenty feet

distance without glasses, and that even a convex glass of $\frac{1}{6}\frac{1}{0}$ was refused for distant vision. Through a strong convex glass, she could not read beyond its focal distance. A weak concave glass seemed to improve her sight, and repeated testing with the perforated disk always indicated a myopia of $-\frac{1}{4}\frac{1}{8}$.

Ophthalmoscopic examination by the direct method showed decided hypermetropia, which, when tested after the paralysis of accommodation by atropia, was found to equal $+\frac{1}{2}\frac{1}{0}$ in the left eye, and $+\frac{1}{3}\frac{1}{0}$ in the right eye.

This case illustrates the advantage of direct examination by the ophthalmoscope, and the importance of the use of atropia in doubtful cases of refractive trouble.

Hydrophobia or Tetanus? (Gattermann: *Bayerisches Aerztl. Intell.-Blatt*, 1872, No. 41; quoted from the *Centralblatt f. Med. Wiss.*, No. 54, 1872).—A boy, seven years old, was bitten by a dog *supposed* to be rabid. The superficial cutaneous wound made by the bite of the dog on the back of the child's hand was instantly cauterized with nitric acid. The same treatment was applied to a somewhat deeper wound on the left forearm. On the evening of the same day on which the injury was received, the boy, having eaten a large amount of food of various kinds, vomited, and was said to have had some hallucinations. However, no fever could be detected, and, with the exception of a slight pain in the wound of the arm, the child remained perfectly well until the ninth day after the bite. At this time all the symptoms of tetanus set in, which were aggravated by the slightest noise, and accompanied by great dysphagia, so that neither solid nor fluid food could be swallowed. Consciousness was perfect. Two days later, with no alteration of the symptoms, excepting a greater facility for swallowing fluids, death occurred, after the most careful administration of morphia and chloral.

A post-mortem examination of the wound in the arm was all that could be obtained. The bottom of the wound was dry and brownish; no pus in the neighborhood. At two points the fascia superficialis was perforated, and the wound had penetrated the muscular tissue.

The author of the article regarded this case as one of tetanus, notwithstanding the inability to swallow, and not as one of *hydrophobia humana*, in which supposition he is sustained by the short incubation,—eight days,—the high temperature observed during the disease, the tonic spasm of the muscles of deglutition and of the muscles of the trunk, and the persistence of consciousness.

There were three other children bitten by the same dog; but after the expiration of sixty days they were still perfectly well.

The Extraction of Foreign Bodies in the Larynx (by Laboulbéne).—M. Laboulbéne has published, in connection with a case seen by him in the Hôpital Necker, an article in the *Bulletin de Thérapeutique* on foreign bodies in the larynx. We give below the classification and the conclusions arrived at. Foreign bodies in the larynx may be divided, according to their seat, into three classes:

a. Foreign bodies above the glottis { vestibular / ventricular.

b. Foreign bodies within the glottis.

c. Foreign bodies below the glottis.

In regard to their extraction, the following are the rules by which the surgeon should be guided:

1. When the danger from asphyxia is imminent, the trachea should, without delay, be freely and boldly opened.

2. The respiration having been re-established, a diligent search should be made for the foreign body by exploring the larynx, with sounds and the laryngoscope, from below upwards and from above downwards. The entrance of the larynx and the ventricles must be inspected, and for the extraction of the body instruments of suitable strength should be introduced, either through the wound in the trachea or through the larynx.

3. A foreign body within the glottis may not, even if it be of considerable size, cause symptoms of asphyxia immediately.

4. The operation must be done as soon as possible: hope ought not to be given up; for it is never too late to act, even if there be but a slight chance of saving the patient.

Laryngoscopic Operations (C. Michel: *Deutsche Zeitschr. f. Chirurg.*, i. 312–317; *Centralblatt f. Med. Wiss.*, No. 31, 1872).—The case under consideration was one of extensive papilloma, which occupied the anterior third of the inferior laryngeal cavity, and passed in a crescentic shape from the right inferior to the left inferior surface of the vocal cords. It also extended from the right ventricle of Morgagni, and covered one centimetre of the anterior superior surface of the right vocal cord. Two small nodules two or three millimetres in size occupied a position close under the free edge of the processus vocalis and opposite to the external surface of the left glottic ligament. This tumor produced in one year total aphonia. During intonation the glottis remained open. The excrescences on the right vocal cord inserted themselves into it. In about sixteen sittings the tumor was taken away, in one hundred and ten pieces, varying from the size of a pin's head to that of a pea. In one year complete recovery took place; only a small elevation, as large as a pin's head, remained under the angle of the vocal cords, but there was no interference with intonation.

Resection of the Knee-Joint after Gunshot Wounds (Lotzbeck: *Aertzl. Intell.-Blatt*, No. 31 u. 32, 1872; quoted from the *Centralblatt f. Med. Wiss.*, No. 38, 1872).—In order to form a just estimate of the practical value of resections of the knee-joint in the field, Lotzbeck has collected all cases of such operations which are scattered through the surgical literature of Germany.

Before the late war, 50 cases, with 35 deaths,—70.0 per cent. In the late war, 16 cases, with 13 deaths,—81.3 per cent. Total, 66 cases, 48 deaths: mortality, 72.8 per cent.

If we compare the amputations of the femur in the lower portions of the bone, with resections of the knee-joint, we shall find that the advantage is in favor of the former; for the mortality is only 60 per cent.

In addition, we must also consider that the limb after resection is not very useful. The author thinks that in the field the amputation of the femur at the lowest possible point is preferable to resection of the knee-joint.

Foreign Body in the Œsophagus (by Cauchois: *Le Mouvement Médical*, Nov. 9, 1872).—A man, 27 years of age, was suddenly, and without any known cause, taken with dyspnœa, pain in the throat, and cough unaccompanied by expectoration.

Examination of the patient's throat and lungs, made on the 25th of August, when he was admitted into the Hôpital Lariboisière, was attended with negative results.

A goitre was observed, which had existed since the patient was a child, but it was too movable and too small to exert any pressure upon the trachea. Attacks of dyspnœa recurred, and the patient died suddenly.

At the autopsy, a foreign body, the nature of which was not determined, was found in the œsophagus, pressing upon the posterior part of the larynx.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 22, 1873.

EDITORIAL.

THE HARVARD MEDICAL SCHOOL.

AMONG the changes constantly taking place in the development of our national character, those affecting the various departments of our educational system are of marked importance. By no means the least decided of these are observable in the training of our young men for the medical profession. A comparison of the advantages offered to the students of twenty, nay, of ten, years ago with those enjoyed by the students of to-day, at any of the leading schools, will show a very marked improvement, which cannot but make itself felt in the standing of the graduates in the community.

The managers of the medical department of Harvard University are trying, we should like to believe with satisfactory prospects, a system of teaching radically different from that of any other school, at least in this country. They have substituted for the usual winter session an academic year, beginning on the Thursday following the last Wednesday in September, and ending on the last Wednesday in June, being divided into two equal terms by a recess of one week; there is also a week's recess at Christmas. Besides this, instead of a yearly repetition of the same course of lectures on each branch, the studies are so arranged as to carry the student "progressively and systematically from one subject to another, in a just and natural order;" the entire curriculum extending over three years.

Laboratory work is substituted for, or added to, the usual didactic lectures on anatomy, histology, chemistry, and pathological anatomy. The examinations are distributed, for the regular students, over the whole three years; but others, as, for example, those desiring the *ad eundem* degree, may pass one final examination at the end of their course. The classification of the students is made upon obvious principles.

Another feature of the Harvard plan is the institution of a course of instruction for graduates in medicine, whereby they may acquire still further proficiency in various special subjects.

This experiment, which went into operation September 28, 1871, has not yet, it is obvious, been fully tried. The "third course," of gratuitous instruction to those who had previously attended two courses of lectures, ceased last autumn. No one will be allowed to graduate under the old system after February, 1874. But the result, whether successful or unsuccessful, of this bold attempt to carry out reform in medical education, will be looked for with interest by the many who have for years discussed and heard discussed, *ad nauseam*, that much-vexed question. It is by such experiments that a practical solution of the difficulties which hedge the whole subject can be arrived at.

And yet there is one most important element,—the financial,—which threatens to fatally affect the success of the Harvard school. If they can keep their classes up, and increase them by the evident value of their teachings, the Faculty may hope to find their efforts rewarded by a brilliant result. If a sordid economy on the part of students leads them to seek schools where lower fees are charged and a less expenditure of time is required, then, for this once at least, the experiment will fail. We believe that it would have been better had the Faculty, if possible, obtained from the munificence of their townsmen an ample endowment, so as to remove this chance of ill-success.

Prof. Stillé, in an admirable address recently delivered before the Alumni Association of the Medical Department of the University of Pennsylvania, thus alludes to this matter: "One institution, to its honor let it be spoken, has re-formed its whole plan of teaching upon the model which reason and experience agree in approving as the best. Much as I desire in this instance to be a false prophet, I have little fear of meeting with the fate of one, when I declare with unfeigned sorrow my conviction that the Medical Department of Harvard University, which has heroically undertaken so difficult a task without providing endowments for its professors' chairs, must of necessity fail to secure the success which its liberal policy deserves."

DIRTY STREETS.

FOR nearly three months the layer of snow which has covered our streets has buried up a vast amount of filth, which the inefficiency of contractors had allowed to accumulate, and which, in the form of most offensive dust, the wild March wind is now scattering over everything. Assuredly the people of Philadelphia are long-suffering to a wonderful degree: they placidly watch the awarding of contracts to men who do not fulfil them, and the struggles of those men to obtain the money they have not earned, as if there were no such thing as taxes, and dirt was a luxury, and the great problem was how to have the worst condition of streets at the highest price.

As the days grow longer, and the sun hotter, and the city more and more offensive, we may look for the natural results of this neglect of cleanliness, in the development of disease. In the long run it would be far cheaper to put an end to jobs and contracts,—to sell the street-dirt to those who would find their interest in its efficient removal, and to regain our long-lost reputation of having a clean city to live in and to welcome strangers to.

CAPITAL PUNISHMENT.

ONE of the outgrowths of modern civilization is a very natural disgust at the roughness and violence of the mode in which the extreme penalty of the law is enforced. And this feeling, which seems to have a certain humanitarian basis, although the "deep damnation of the taking off" of the murderer's victim ought to counteract it, is rather growing than subsiding.

It is therefore strange that modern science has not sought to substitute for the rope or the axe less rude methods of taking forfeited lives. Every schoolboy knows how calmly Socrates took his cup of poison, and with what philosophy he watched the gradual approach of death. The gallows and the guillotine are features of a ruder age than that of Grecian refinement.

Why cannot condemned criminals spend their last moments in a room in which carbonic acid is generated, by the well-known means, until life is extinct? The very silence of the process would be impressive. The murderer would simply cease to exist among men, without any opportunity for bravado, without pitting his power to endure against a stronger power to torture. The law would be vindicated, and the brute courage of the "game" convict would have no chance to infect his associates.

LEADING ARTICLES.

INSANE CONVICTS.

WE understand that a bill has been introduced into the Senate of this State for the purpose of placing in the insane hospital at Danville the insane convicts now scattered about in the jails and penitentiaries of the State. It is one of those measures which, originating in a most commendable philanthropy, are marked by such an imperfect knowledge of the conditions of the case that they are calculated to do more harm than good. This, at the very best, would substitute for one evil another and a greater. We would call attention for a moment to some of the consequences of this measure, in the hope of staying any farther progress in the movement.

A great majority of this class of criminals are people of very small moral and intellectual endowment, whose criminal acts have been prompted more by innate depravity than by insanity; though we would not deny the agency of the latter element. Some of them have even achieved distinction in the records of crime, and all are marked by a stigma that affects the whole course of their social relations. The promoters of this measure think to avoid the social objection, which they seem to have anticipated, by having a portion of the hospital insulated from the rest and prepared expressly for this purpose. But this is not sufficient. In the popular apprehension, the main features of the association remain as prominent and as odious as possible. The inmates, convict and otherwise, are all under the same roof, seeing and hearing one another, more or less, in an establishment and locality bearing the same name, and participating in some degree in common privileges. Now, on the part of those who seek the benefits of our State hospitals for the insane, there is a sensitiveness in regard to such associations which cannot be allayed by any architectural contrivances, and which will prove a very serious impediment in the way of an early resort to the hospital for curative purposes. For it must be remembered that, for the most part, though in humble circumstances, they are respectable, and not entirely destitute of a wholesome pride.

Practically, there is little similarity between the management and discipline of a hospital and those of a prison. Nobody has ever proposed to abolish this distinction, and to treat the convicts precisely like other patients. While the latter are to be treated with the utmost kindness and courtesy, and allowed the largest amount of liberty and indulgence

compatible with their comfort and restoration, the former are to be habitually treated as dangerous subjects, allowed few of the privileges accorded to other patients, and kept within the narrowest limits. The spirit, disposition, and manners required of an attendant on the former class of patients would be quite unsuitable to an attendant on the latter class. For it must be borne in mind that in regard to many, insanity has deprived them of none of their native cunning, nor of their disposition to mischief, nor of their impatience of restraint. They must constantly feel the strong hand. Now, it is idle to suppose that two such classes of attendants will serve side by side and continue to maintain the proper difference in the treatment as here indicated. The tendency would be to assimilate; and it requires no great knowledge of human nature to see what direction it would take. In an institution receiving both classes of patients, the treatment would be uniformly hard, rigid, stern, and peremptory for both.

The management of a hospital for insane convicts, in order that it may present as little of the prison and as much of the hospital element as possible, is so peculiar that it is a specialty of itself quite different from that of an ordinary hospital. We have great faith in the resources of Dr. Schultz, but we do not believe that he pretends to be fitted by taste or training to take charge of such an institution; and even if he were, it would be out of his power, with some three or four hundred others to treat, to do justice to the convict patients.

It is well known that our hospital accommodation for the insane is lamentably deficient, and consequently that many hundreds are suffering every variety of wretchedness in the jails and almshouses. It was for such that, after persevering effort, the hospital at Danville was obtained; and now that it is about ready to receive them, they are to be thrust aside to make room for those who would always prove a heterogeneous and disturbing element. The scheme is prompted ostensibly by the purest benevolence; but where the kindness comes in we are quite unable to see. Nor does there seem to be any foundation for the economical consideration. To construct a convict hospital *de novo*, by itself, would cost little if any more than it will to convert a portion of the Danville hospital into one. To be suitable for its purpose, capable of keeping its inmates safely, and affording them all possible comforts and privileges, it must consist of no makeshifts, but every portion of it, from foundation-stone to roof, must be marked by indications of its destined purpose. Not more different must it be from other hospitals in its management and discipline than in the mode and materials of its construction. The safe-keeping of the inmates is a matter of paramount importance, because many of them are dangerous subjects, ready and willing to break out when guarded only by the ordinary methods of construction.

The obvious duty of the State is to do precisely what New York and several European countries have done, viz., to establish a hospital expressly and solely for insane convicts. The bill we have been commenting on provides for fifty persons,—a number large enough to start with in a new establishment,—and for this number it might cost one hundred thousand dollars. To make the proposed changes at Danville would cost little less, and, after all, it would only be converting a good hospital into a poor prison. We trust, therefore, that the Legislature will be slow to adopt a measure not in accordance with the best views and practices now prevalent on the subject, and directly detrimental to a large class of our suffering fellow-men.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, FEBRUARY 13, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. R. M. BERTOLET exhibited a specimen of *psammoma* removed from a gentleman aged about 40 years. (A full report of the case will appear in a subsequent number of the *Times*.)

Dr. CHAS. B. NANCREDE presented a specimen of *aneurism of the abdominal aorta*, from C. H., æt. 33 years. The patient from whom this specimen was removed first came under notice about eighteen months ago, at the Eye Department of the Philadelphia Dispensary, and complained of failing vision which had come on quite suddenly.

Upon examination by the ophthalmoscope, the *fundi* of both eyes were invisible, owing to a clouded condition of the vitreous tumor. Upon questioning, this was found due to syphilitic retino-choroiditis, the patient having confessed that he had had a chancre a number of years before, a skin-eruption since, and was then troubled with osteocopic pains.

He also had polyuria, which in time decreased. The urine was examined several times, but neither sugar nor albumen was detected.

Under specific treatment, his vision improved, the cloudiness of the vitreous having commenced to disappear; but about four months after the time when first seen, violent convulsions set in, accompanied by unconsciousness lasting for twelve hours. He entirely recovered under the use of large doses of potass. iodid. The convulsions were thought to be due to a specific tumor at the base of the brain. He continued to improve, with but few relapses, under the above treatment and Turkish baths, until within nine months of his death, when he first complained of a violent pain in his back, but was

not able to locate it exactly. He also had dyspeptic symptoms and some dysphagia. In swallowing fluids he was obliged to take small quantities at a time, as they seemed to accumulate above the cardiac orifice.

By increased doses of the iodide, and rest in a hospital, this pain in the back was greatly relieved, but it was still at times so severe as to incapacitate him for work, and generally to necessitate a sitting posture during sleep. The day before the patient's death he seemed rather worse, but continued to work; but the day following he was too unwell to do so, complaining of great pain in his right side. In the evening, about ten minutes before death, he attempted to go to stool, and, on trying to return to bed, sank on the floor and expired some minutes before I reached him.

Sectio cadaveris, thirty-nine hours after death.—Rigor mortis well marked; body well nourished, but exceedingly blanched.

The head was first examined. Vessels of scalp empty of blood; veins of the dura mater unusually full; pia mater showed the remains of a former inflammation, old lymph, etc.; brain-substance firm, showing numerous red points on section; a little fluid in lateral ventricles; some old lymph on velum interpositum. Pineal gland enlarged, having undergone mucoid softening; there was old lymph at base of brain, especially at the optic chiasm.

On opening the abdomen, an enormous clot, an inch or more in thickness, extended from the liver into the pelvis, and forward to within two inches of the median line, pushing aside the viscera. This clot was from an aneurism, which had burst primarily into the subperitoneal connective tissue beneath the cardiac orifice of the stomach. This morbid growth had produced no erosion of the vertebræ, probably because of the short time it had existed.

The aneurism was sacciform, extending from about the origin of the phrenics nearly to that of the inferior mesenteric artery. The radials at the wrist could easily be felt, showing that there must have been some degeneration of their walls. The right kidney was twice the normal size, and slightly granular. The left was smaller than normal, its capsule non-adherent, and under the microscope exhibited numerous tubules stripped of their epithelium.

The main points of interest in this case would seem to be the aneurism with the syphilitic dyscrasia, and the peculiar place of rupture, viz., the subperitoneal space. That a number of hours should have intervened between the time of primary rupture and death is remarkable. This rupture probably took place beneath the peritoneum, in the morning when he first complained of pain in the side, he having gone down into the yard to stool, and must have been small at first, gradually dissecting up the peritoneum, producing intense pain. The straining during the last act of defecation must have enlarged the opening in the sac. The peritoneum then gave way, and a large quantity of blood was suddenly effused into the abdominal cavity, producing sudden death both from the amount lost and the shock of the injury.

Dr. H. Lenox Hodge exhibited a specimen of *bony anchylosis of the right hip*. No history could be obtained. The femur was of large size, but the ridges for muscular attachments were slight and smooth. The muscles of the thigh therefore could have been but little used. The neck of the femur was slightly shortened. The head of the bone was firmly united to the acetabulum, and rested at the anterior and upper portions. The os innominatum was comparatively small, and not so well developed as the femur.

The position of the united bones was such as to produce adduction and outward rotation of the femur.

The specimen is interesting chiefly in reference to the operations lately revived and suggested for restoring the usefulness of the limb when anchylosed in such a position as to render it useless. Dr. Barton made a section of the femur between the trochanters. Dr. Rodgers removed a segment of bone at the same location. Dr. Sayre has also removed a segment of bone from the same position, but rounded the surfaces so as to leave a concavity on the upper fragment to meet a convexity on the lower fragment of the femur. In these operations large external incisions were made to expose the bone. Mr. Adams in 1869 divided the femur subcutaneously by means of a small saw made after the form of a tenotomy knife. This plan appears to have greatly reduced the dangers of the operation; but it gives less promise of a movable joint. After the other operations motion was not always obtained, and has been lost even after six years, as in Barton's case. If the limb be restored to a good position, it becomes very useful, although there may be no motion. The operation of Mr. Adams is to be preferred, as it is less dangerous, is less apt to be followed by necrosis, and gives a useful limb. Mr. Adams divides the femur through the neck, while the others have sawn it between the trochanters. If the anchylosis be really bony, one position is probably no more dangerous than the other. If the deformity be chiefly due to flexion of the thigh on the pelvis, it will be overcome with the least possible displacement of the fragments from each other by making the section through the neck of the femur. If, however, the deformity be due chiefly to rotation of the limb, there will be less displacement when the section is made between the trochanters.

Dr. John Ashhurst, Jr., said, in answer to a question, that he thought it very doubtful whether bony union was ever met with in cases of unimpacted intra-capsular fracture of the cervix femoris; many specimens, which had been supposed to exhibit osseous union after fracture, had been found when sawn open to be examples of other lesions entirely unconnected with fracture, while in other examples it might be that, as in a specimen referred to by Prof. Sayre,* the ligamentous connections were so close and firm that, in the dry condition, osseous union was simulated. In cases of *impacted* fracture, however, Dr. Ashhurst had no doubt that true bony union could occur; in fact, there was a specimen in the museum of the College of Physicians,† which had been reported on by Dr. Packard, Dr. Hewson, and himself, which illustrated this condition; and other examples were mentioned by Prof. Bigelow,‡ of Boston, in his well-known work on injuries of the hip.

Dr. J. H. Hutchinson presented specimens of *tubercular ulceration of the larynx, amyloid kidney, and amyloid and fatty liver*, from a woman, æt. 40, dying of phthisis. (A full report of the case will be published later in "Hospital Notes" of this journal.)

Dr. Joseph G. Richardson said that, notwithstanding the increased quantity of connective tissue about the Malpighian corpuscles, there was no diminution in the size of the latter. He suggested that this might be due to the presence of amyloid matter in the capillary tufts of the body resisting the contraction which usually occurs.

Dr. James Tyson asked Dr. Hutchinson whether he thought there was any necessary relation between the amyloid degeneration and the increased amount of intertubular connective tissue, or whether the two conditions were not merely coincident. He doubted whether the so-called amyloid matter ever became fibrillated.

Dr. Hutchinson thought there was a causal relation.

Dr. Richardson said that he considered the amyloid matter might act as an irritant, causing proliferation of the intertubular connective-tissue element; in which

Dr. Hutchinson concurred.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

Reported by JAMES S. BAILEY, M.D.

SPECIAL MEETING, February 25.

A MEETING was called for the purpose of taking suitable action in reference to the death of Dr. Uriah G. Bigelow, a member of this Society for the last twenty-seven years. Appropriate remarks were made by the president and many of the older members of the profession. The Society then adjourned to meet and attend the funeral in a body, February 26.

SEMI-MONTHLY MEETING, February 26, 1873.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

The subject for discussion was *paracentesis thoracis*, a paper on this subject having been read by Dr. E. H. Davis. (See this journal for February 15, 1873, p. 316.)

Dr. HENRY MARCH reported eleven cases as having been operated upon by his father, the late Dr. Alden March. The relief to five of the cases was only temporary, they having died within a few months with tubercular phthisis. One died with cancer of the lungs. Nine were adults, and two were children. In four cases there was serum in the chest; in three, pus; the rest, sero-pus. In all the cases the trocar was used.

Dr. M. M. LAMB reported the following case of *spontaneous* effort of nature for the relief of empyema. L. N., æt. five years, six months ago had scarlet fever, which seemingly terminated favorably, but was subsequently followed by diarrhœa, cough, and general wasting of the tissues of the body. There was dyspnœa. In three months from the attack an abscess formed about the fifth rib, which broke, and a quart of pus escaped. The child now seems well and fat, although the fistula still remains unhealed and a slight discharge of very offensive matter still escapes through the opening.

Dr. JOSEPH BLATNER then read a translation from the German, by Oppolzer, upon this subject.

Dr. WILLIAM HAILES gave the history of a man who enlisted in the army in 1861, who had an attack of pleuro-pneumonia. When several weeks had elapsed, the physical signs indicated pus in the left side. He was operated on between the fifth and sixth ribs, and the fistula remained open for several years, the patient enjoying fair health during this time. Two and a half years ago it closed, and the matter collected again. An operation was performed the second time in the sixth intercostal space. A gum-elastic catheter was introduced, and the cavity injected with warm water and a few drops of carbolic acid by means of a Davidson's syringe. The man did well, and in a few weeks was enabled to leave the hospital and return home. Three months ago he died with tubercular phthisis of the right lung; the left lung was atrophied, and the pleura was greatly indurated and thickened.

The ribs were on this side much contracted with a slight lateral curvature of the spine.

He then related the case of an incised wound through the pleura. A man in an altercation was struck upon the scapula with the point of a sharp knife, which was reflected along until it slipped through between the ribs and penetrated the pleura. Emphysema took place, which in a few days subsided, and the breathing became natural. In a little more than a week the patient was discharged.

The PRESIDENT then referred to the establishment of thoracic fistula which takes place in nature in the healing of gunshot wounds. He then referred to eleven cases, coming under his observation, of gunshot wounds in the chest during the war. Nine recovered, and two died. The track of the bullet healed without pus. One recovered in two weeks. In seven that recovered, empyema and pus flowed through both openings. All of them were relieved in the course of a year.

Dr. VAN DERVEER then exhibited a pathological specimen of effusion of blood in the brain, with the following history. J. S., æt. 65, an intelligent man, had studied both medicine and law, but was fond of wine, etc.; had lived an irregular and, for the past year, a sedentary life. He was a steady drinker. February 21, he retired to bed in usual health, and towards morning aroused his family by stertorous breathing. The doctor was summoned, and found it a case of cerebral hemorrhage. The left side was paralyzed. The right eye was sensitive to light, but the left eye was not. He lived until Tuesday, the 25th, when he expired. The autopsy revealed the remarkable fact that, considering his habits and exposures, there were no pleuritic adhesions. The right lateral ventricle was filled with blood, and the brain-substance was bored through to the surface by the pressure. The left lateral ventricle also contained bloody serum.

Dr. JAMES S. BAILEY reported a case of *meningocele*, and exhibited photographs of the same. This case occurred in the practice of Dr. M. M. Lamb, of Lansingburg, and he was indebted to him for the following history.

This child was one of twins, one being without deformity. The child lived fourteen days from birth, and continued to nurse until a few hours before death.

The tumor was one-third larger than the child's head, and its external surface had much the same appearance as the scalp, being slightly covered with hair. Internally it was covered by the membranes of the brain distended with subarachnoidean fluid.

Dr. JAMES S. BAILEY also presented a case of *lipomata*, or fatty tumors of the abdomen, occurring in the person of a German woman aged 69, causing her death by pressure and absorption of the surrounding viscera.

Two tumors, weighing together thirty-seven pounds and two ounces, occupied almost all of the abdominal space. The hereditary tendency referred to by Erichsen was observed in this family. A sister three years younger than the deceased was likewise afflicted; also a daughter, who had just passed the meridian of life.

REVIEWS AND BOOK NOTICES.

A TREATISE ON APOPLEXY, Cerebral Hemorrhage, Cerebral Embolism, Cerebral Gout, Cerebral Rheumatism, and Epidemic Cerebro-Spinal Meningitis. By JOHN A. LIDELL, A.M., M.D., etc. 8vo, pp. 395. New York, William Wood & Co., 1873.

We think the modest hope of the author, as expressed in the preface to this excellent monograph, that it will prove interesting and useful to those who read it, will be fully realized. Originally intended for insertion in a medical journal, the essay grew in the course of its preparation to a bulk exceeding the limits of any such channel, and its issue in a separate volume was wisely determined upon.

Dr. Lidell, after quoting the various definitions of apoplexy, as given by standard authors, offers the following: "Apoplexy is a disease of the brain which is characterized by the sudden abolition of consciousness, feeling, and voluntary motion, and is produced not by injury, nor by poison, nor by heat, but by some morbid action in the brain itself."

"It essentially consists," says he, "in the sudden occurrence of complete functional inactivity of the cere-

brum, as a consequence of disease." He justly objects to the use of this term to designate extravasations of blood in the lungs or elsewhere, especially on the ground that in the brain it does not by any means imply hemorrhage.

The varieties of true apoplexy are—congestive, serous, hemorrhagic, embolic, and nervous. Besides these there are certain special forms,—meningeal, infantile, gouty, and rheumatic.

In Chapter II., on the pathogeny of this disorder, our author inclines to the view that it is substantially a condition of anæmia, the brain being embarrassed, by pressure or otherwise, so that the due amount of blood cannot be taken up and utilized by it for the purpose of its nutrition and due performance of function.

A very interesting discussion of the causes of apoplexy, in Chapter III., contains some striking facts as to the influence of sex, of age, of the use of alcoholic liquors, of hereditary predisposition, and of various diseases, in favoring its occurrence.

The succeeding chapters, on the various forms of the disorder, are to a very large extent clinical, containing notes of sixty-two cases, with autopsies, forty-four of which occurred in Dr. Lidell's own experience. We should be glad to make copious extracts from the fund of information and sound reasoning in these pages, but our limited space forbids, and we really are at a loss to select any passage to the value of which the context would not be essential. We shall confine ourselves to adducing some of the statements of our author as to epidemic cerebro-spinal meningitis.

This, he contends, is not an idiopathic, primary, or essential fever, but a local phlegmasia, upon which alone the febrile excitement, when present, and all the other symptoms, depend. It may follow other diseases, such as pneumonia or camp diarrhœa; or surgical operations, or exposure to intense cold. It differs materially from typhus and from the ordinary paludal fevers. A recent outbreak of it in New York seemed to be traceable to (1) lowness of temperature; (2), humidity of the ground and atmosphere; (3) foul sewer-gases and imperfect house-drainage; (4) over-crowding and attendant evils; (5) want of adequate house-ventilation.

We must now bring this brief notice to a close, heartily recommending the work of Dr. Lidell to the profession as one of very great value, and hoping that he will soon give us further instalments of his "quota of work," as in his preface he promises to do.

A Treatise on the Theory and Practice of Obstetrics. By William H. Byford, A.M., M.D., etc. Second Edition; Thoroughly Revised. 8vo, pp. 465. New York, William Wood & Co., 1873.

Arbolan, the Moorish hero of many a Spanish ballad, was a diamond among scimetars, and yet graceful in the dance:—

> "Diamante entre los alfanges,
> Gracioso en baylar las zambras."

Very few medical writers of the day resemble Arbolan the Moor. Of those few Professor Byford is not one; for, however cunning with the scimetar, in the dance of style he exhibits but little grace. Yet in this the second edition of his work on obstetrics he has more than redeemed the pledges given in the preface. He has certainly "improved the occasion to thoroughly revise the whole and rewrite a portion of it. He has also made quite a number of additions which he thinks [and we think so too] will increase the worth of it."

So superior is this edition to the first that we should hardly have traced any kinship between them, were it not for certain wood-cuts which had impressed themselves indelibly upon our memory. One of them (Fig. 125) so successfully resembles nothing in the heaven above, or in the earth beneath, or in the water under the earth, that the worship of it by the Ten Tribes—including the half-tribes of Manasseh—would have saved them from the penalty of dispersion. We recommend it to Exeter Hall for exportation by the bale to Central Africa.

Notwithstanding the care plainly exhibited in the preparation of this work, we could point out many queer errors in the agreement and government of words. But this we shall not do: we are too loyal to our medical literature to cast any discredit upon an excellent manual of obstetrics, simply because its author is not well grounded in the humanities.

GLEANINGS FROM OUR EXCHANGES.

Hereditary Syphilis of the Bones of the New-Born (L. E. Dupuy, in *Le Mouvement Médical*, December 28, 1872):

1. George Wegner. Osseous Lesions in Young Infants, caused by Hereditary Syphilis: *Virchow's Archiv*, 1870.

2. Köbner. Vaccinal Syphilis: *Archiv für Dermatologie und Syphilis*, 1871.

3. Parrot. Pseudo-Paralysis caused by an Alteration of the Bones of the New-Born affected with Hereditary Syphilis: *Archives de Physiologie Normale et Pathologique*, May, 1872.

4. Waldeyer and Köbner. Hereditary Osseous Syphilis: *Virchow's Archiv*, August, 1872.

The observations of Valleix, Barpoin, Ranvier, and Guéniot have drawn attention to an alteration of the osseous system of new-born children affected with hereditary syphilis. This alteration is constantly manifest even to the naked eye, and is very distinct microscopically; and hereafter the diagnosis of hereditary syphilis can be reduced to a certainty, even in the absence of visceral or cutaneous lesions. The importance of this discovery will not escape any one: in a therapeutic point of view in syphilis of the parents, where the diagnosis is doubtful, it will become possible to institute a rational treatment with perfect knowledge of the cause; in a medico-legal point of view it can be distinctly affirmed whether or not the new-born child is affected with hereditary or acquired syphilis. Finally, M. Parrot has shown that the progress of the alteration of the bones may, by causing a separation of the epiphyses, produce a pseudo-paralysis or loss of power, more or less complete, of the limbs. What, then, are the characters of these alterations of the bones? Throwing aside the sub-periosteal lesions, which are not constantly present, we will draw attention to the changes seen on section of the long bones. The description given by M. Parrot is so remarkable that we will give it in full.

These alterations affect the extremities, and attack the epiphyseal cartilage and the diaphysis. It may be said that they represent in their entirety an amplification of the physiological arrangement; this, in the wolf, is to a certain extent the normal condition. Thus the cartilaginous plate is much thicker than usual; it may be doubled, even quadrupled. Its transparency and softness are very marked. Its consistence, which is not everywhere the same, varies from that of the crystalline to that of the vitreous body; and it is only in very circumscribed points that it approaches the latter. Sometimes the border forms a prominence in the shape of a cushion (*bourrelet*). What is most striking, and characteristic indeed, is the cartilagino-calcareous zone. It differs much from that which normally exists, in its thickness, which is much greater, since it may attain two millimetres, but above all in its yellow-gray or even

whitish color, giving it, even in the fresh state, a chalky appearance. Instead of being distinctly defined by a straight line or gentle curve, as in healthy bones, it is very wavy or dentated, and sometimes sends prolongations towards the cartilage and towards the spongy tissue. It is also remarkable for its friability, which notably diminishes the adherence of the epiphysis to the bone.

The neighboring spongy tissue, with a thickness rarely exceeding fifteen or twenty millimetres, has undergone changes in color, and this in a very irregular manner. There are seen grayish surfaces, with spots of a more or less deep rose tint, and surfaces of a whitish or yellowish color.

When the disease is recent, the lesions, generally speaking, are limited, but when it is of longer duration they become better pronounced, and others are seen to appear. They consist, in general, of a destruction of the bony substance; affecting at first the spongy tissue, and later the compact layer itself. This result is brought about in different ways, and the parts involved present different appearances. In some individuals the processes go on separately, in others they are probably in combined operation; but it is difficult to distinguish them among the phenomena of the later stages. We shall point out the two principal, and state how they present themselves. One of them may be called gelatiniform softening. It does not ordinarily occur at the onset, being preceded by the appearance, in the neighborhood of the cartilagino-calcareous layer, of little islands of tissue, analogous to that called spongoid in rachitis. These islets may occur alone, but sometimes they cover a space of variable extent, when the bony substance is replaced by a very soft material varying in color from amber-yellow to reddish-brown, and endowed with a certain degree of transparence. It is readily perceived, by dissection with a needle, that its frame-work is fibrous and fibro-vascular, and sometimes that little bony fragments are enclosed. It may form, at the extremity of the diaphysis, a decidedly thick layer; but in the majority of cases it is very unequally distributed, occupying sometimes the centre and sometimes the periphery of the extremity of the diaphysis. On exposure to the air it completely breaks down by desiccation, leaving a cavity with quite regular outlines. In the other form a yellow substance looking very much like pus infiltrates the spongy tissue. The bony layers do not usually escape. They break down and finally become completely destroyed. A more or less extensive loss of substance follows, with the formation of cavities filled with a puriform fluid. This occurs in the neighborhood of the epiphysis, and the cartilage, if it be thin, may become destroyed. Very often there are bony fragments or true bony sequestra in the middle of the yellowish substance. It can be readily understood that this process of ulceration causes a somewhat rapid separation of the epiphysis from the diaphysis, just such as we have seen produced in the gelatiniform atrophy.

The break, in either case, does not usually occur at the cartilagino-osseous juncture, but at a point very near the diaphyseal extremity. The surfaces of the fragments are uneven; and a portion or even the whole of the chondro-calcareous layer remains adherent to the cartilage.

When the macroscopical characters are slightly marked or absent, we always find characteristic anomalies by means of the microscope. The most recent description of these histological alterations has been given by MM. Waldeyer and Köbner, who, besides confirming former observations, have made certain unexplained points more clear. The following is a résumé of their researches:

In the first place we notice a more active proliferation of cartilage-cells at the boundaries of ossification; the newly-formed cells are small, rounded, analogous to those of syphilitic production. The cartilage and zone of ossification encroach upon one another by irregular dentations; the latter arrangement is characteristic. The medullary spaces of the spongy layer of Guérin are filled with a peculiar granular tissue, difficult to describe, such as is met with in syphilitic changes in other organs, and consisting of small, rounded, angular, or fusiform elements. The consistence of this tissue varies; sometimes we find soft puriform masses, and sometimes formations of a harder character. True pus is never seen. The tissue, contrary to the opinion of Wegner, is very vascular. Finally, Waldeyer has always observed the entire absence of osteoplasts, which are replaced by small granular cells or by fusiform elements.

Sudden Grayness of the Hair (J. Pincus: *Wiener Med. Presse*, No. 2, 1873).—The author has gleaned the following facts relating to this interesting phenomenon. One case, that of a physician in Berlin, he gives in the sufferer's own words, as follows:

"My wife and daughter had gone to spend the summer in one of the neighboring baths. I was awaiting a letter informing me of their arrival and domestication in their new abode. The expected letter arrived as I was about to drive in company with my oldest daughter.

"I opened the letter, and read that my daughter had suddenly died. Instantly my hair became gray, with here and there a remaining brown one. I had to go that afternoon into the country to visit some patients, and I met those I knew, and who had seen me twenty-four hours before. They were astounded to see I had turned gray 'in a night.' I must state that I was then, always have been, and am still, a strong and healthy man."

Another case emanates from the Netherlands, on the authority of Dr. Kooman:

"A young man thirty or thirty-five years old, with black hair and beard, was in the habit of visiting me. One day he came into my office, and I was at a loss to recognize the man who stood before me, for it was my friend with hair and beard white as snow. He saw my surprise, and told me the following tale. A few weeks previous to his visit to me, while passing through the streets and canals of Rotterdam he saw a crowd of people excited and calling for help. As he drew near, he heard that a little boy had fallen into the canal. Being a good swimmer, he jumped into the water and rescued the boy, but life was extinct. He at the same moment recognized the lad as his own little son. Instantly his hair became gray."

In this instance the physician who noted the case stated that the individual hairs became gray throughout their entire length, and not merely at their roots. In such cases the author has thought that the rule is for the hairs which grow after the date of the shock to become gray, while that which is black at the time of fright remains black.

MISCELLANY.

At a conversational meeting of the Philadelphia County Medical Society, held February 25, 1873, the following resolutions, offered by Dr. H. H. Smith, were unanimously adopted:

"Whereas, It has pleased Divine Providence to remove to a happier sphere one of the most honored members of our Society, who, during a long and useful life, has ever been noted for the purity and benevolence

of his character, not only as a physician but also as a citizen of Philadelphia: therefore

Resolved, That the Philadelphia County Medical Society have recently learned with deep regret of the sudden and unexpected death of Dr. Hugh L. Hodge, Emeritus Professor of Obstetrics in the University of Pennsylvania, and one of the oldest members of this Society.

"*Resolved*, That by the death of Dr. Hodge this Society has lost a highly-esteemed member, whose skill and erudition had gained him a world-wide reputation as an accoucheur, and made him an authority in difficult cases that greatly relieved the anxious hours of his juniors, who were often led by his courtesy and high professional honor to avail themselves of his valuable assistance.

"*Resolved*, That the members of this Society, most of whom have been his pupils, recall with pride and pleasure the sound and practical precepts inculcated in his teaching.

"*Resolved*, That Dr. Wm. Goodell be requested to prepare a biographical memoir of our late member, to be read before this Society.

"*Resolved*, That the Philadelphia County Medical Society respectfully tender to his family their sympathy in their affliction.

"*Resolved*, That these resolutions be engrossed on the minutes of the Society and published in its transactions, as well as in two of the daily papers of the city, and that a copy signed by the officers be transmitted to the family of the deceased.

"*Resolved*, That, as a token of respect, this Society do now adjourn until Saturday, March 1, 1873, at two o'clock P.M., when they will meet at the Second Presbyterian Church, Twenty-first and Walnut Streets, to attend the funeral ceremonies."

DR. WILLIAM W. RUTHERFORD, an eminent physician of Harrisburg, died in that city March 13. He was born in the neighborhood of the State capital, in November, 1805, and graduated at the Jefferson Medical College in this city in 1832. For forty years past he had practised his profession with great success in Harrisburg, and since 1862 had held the position of Surgeon to the Pennsylvania Railroad Company. Dr. Rutherford was a man of the most generous disposition, and was always found ready to minister to the suffering poor, without compensation, even at the expense of neglecting those who were able to reward his services liberally.

At a special meeting of the Dauphin County Medical Society, held March 14, the following resolutions were adopted:

Resolved, That this Society receives with profound sorrow the announcement of the death of Dr. W. W. Rutherford, its oldest member.

Resolved, That, while no brief lines can do justice to his worth, we cannot allow this occasion to pass without recording our appreciation of one who, whilst a member of this Society, had been our associate, our president, and our representative to the State and National Medical Associations, thus filling all the positions of honor and confidence in our gift. He has passed away, and multitudes will mourn him: those to whom in trying hours of sickness he ministered with mingled kindness and firmness and energy; those who could understand the sterling character that underlay a sometimes "brusque" manner; those who gathered in affection around his own hearthstone; those of *us* who have admired his professional and social qualities, and who will greatly miss his counsels;—these are *some* of those who will mourn his loss and keep his memory green.

Resolved, That we tender to his bereaved family our warmest sympathy.

Resolved, That this Society attend his funeral.

H. B. BUEHLER, M.D., *Secretary*.

COMMENCEMENTS.—The Jefferson Medical College held its annual commencement on Wednesday, March 12, with a graduating class of 149. The valedictory address was delivered by Professor B. Howard Rand.

A supper was given to the graduates by the Alumni Association on Tuesday evening, at the Assembly Building.

The commencement of the Medical Department of the University of Pennsylvania took place on Thursday, the 13th, the graduating class numbering 99. The valedictory address was by Professor Francis Gurney Smith.

Prizes were given, two by the Alumni Association, and one by a liberal friend of the University, of $50 each, to the following graduates, for meritorious theses: Henry M. Estrazulas, of Uruguay, S.A., Juan y Gener Guiteras, of Cuba, and John M. Keating, of Philadelphia. A gold medal was given by Dr. H. Lenox Hodge, Demonstrator of Anatomy, to Dr. Henry B. Reed, for industry and skill in dissection, and the sum of $30 by Dr. W. Pepper, Lecturer on Clinical Medicine, to Dr. A. L. A. Toboldt, for clinical reports.

The Alumni Association of the Medical Department of the University gave the graduating class a very handsome supper on Wednesday evening, at the University Buildings on Ninth Street.

CURIOUS SUIT.—A case was recently tried in this city, in which damages were claimed from a physician for the death from smallpox of a child whom he had failed to vaccinate. The plaintiff alleged that in November, 1871, when the smallpox was first pronounced to be epidemic in this city, the doctor was casually asked to vaccinate his child, an infant not quite a year old; the doctor performed the operation, and was paid his fee. The vaccination did not succeed, and the doctor was again called upon with regard to it, but said he had not then any good virus. However, he did not perform the operation again, having been out when the child was brought to him for the purpose; and in March following the child was attacked with the disease and died. Plaintiff claimed that the doctor expressly took charge of the case, and neglected it, first in not vaccinating properly when he undertook the operation in November,

and afterwards in not vaccinating at all when he was required and promised to do it, from which alleged negligence the death of the child resulted; and for this it was sought to hold him responsible in damages. Judgment of nonsuit was entered against the plaintiff.

A Sinecure Professorship.—A correspondent of the *Lyon Médical*, after insisting on the advantages of "the remuneration of the teacher by the pupil," and on the excellent material available in Lyons for the formation of a faculty of medicine, adds that it is indispensable that the school should have a good professorial staff. "The first thing needful," he adds, "is for it to get rid of a member who occupies a chair but does not fill it. What good does this *titular professor* do, who since 1862 *has delivered but one course of lectures*, and for nine years has devolved his work upon a substitute? It is true that this professor, loaded with years, honors, and fortune, generously gives *one-eighth* (!) of the proceeds to his delegate; so that, as Ponsard said, 'he keeps for himself the honors and the money, and leaves all the labor to another.'"

The Executive Committee of the American Public Health Association some time since decided that the annual meeting of that body should not be held, as contemplated, in Washington, about the 1st of March. The time fixed upon is Thursday, May 1, and the place, Cincinnati.

They announce that a circular indicating the order of business will be issued before the time of meeting.

University of Pennsylvania — Auxiliary Faculty of Medicine.—The annual course of lectures will commence on Monday, March 24, 1873. The general introductory will be delivered on that day, at 4½ o'clock P.M., by Professor Samuel B. Howell, M.D.

John J. Reese, M.D.,
Dean of Auxiliary Faculty.

According to the *British Medical Journal*, there are 110 female students attending the present session of the University of Zurich. Of these, 81 are studying medicine, 28 philosophy, and 1 jurisprudence.

Obituary.—John Torrey, M.D., LL.D., a distinguished botanist and chemist, and lately Professor of Botany and Chemistry in Columbia College, New York, died on the 10th instant.

An arrangement has been definitely made by which the female medical students may attend the wards of the Edinburgh Royal Infirmary, on Sundays, with Dr. P. Heron Watson.

Dr. W. Scott Hendrie has been elected visiting physician to the House of Correction.

Mortality of Philadelphia.—The interments reported at the Health Office for the week ending March 15, 1873, were 337; 182 adults, and 155 minors. 9 were of bodies brought from the country; making the mortality of the city 328. Among the assigned causes of death were:

Consumption of the Lungs	52
Other Diseases of the Respiratory Organs	55
Diseases of the Circulatory Apparatus	23
Diseases of the Brain and Nervous System	71
Diseases of the Digestive Apparatus	23
Zymotic Diseases (10 from Scarlet Fever)	19
Typhoid Fever	5
Casualties	7
Cancer	4
Diseases of the Urinary Organs	5
Pyæmia	1
Intemperance	1
Suicide	2
Debility (including "Inanition" and "Marasmus")	36
Still-born	16
Old Age	10

(The interments reported for the week ending March 16, 1872, were 444.)

The meteorological record kept at the Pennsylvania Hospital was as follows:

		THERMOMETER.		BAROMETER.
		Max.	Min.	(2 P.M.)
Mar.	9	51.0°	40.0°	29.78 in.
"	10	41.5	34.0	30.17 in.
"	11	48.0	39.5	29.92 in. (Rain and Hail.)
"	12	42.5	39.0	30.15 in.
"	13	42.5	31.0	30.36 in.
"	14	47.5	32.5	30.51 in.
"	15	62.0	38.5	30.12 in.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 11, 1873, TO MARCH 17, 1873, INCLUSIVE.

Kimball, J. C., Assistant-Surgeon.—Relieved from duty in the Department of the Gulf, and to report to the Commanding General, Department of Dakota, for assignment to duty. S. O. 52, c. s., A. G. O.

Delany, Alfred, Assistant-Surgeon.—Leave of absence extended two months. S. O. 51, A. G. O., March 11, 1873.

Ewen, C., Assistant-Surgeon.—To report to the Commanding Officer, Department of the Gulf, for assignment to duty. S. O. 52, A. G. O., March 12, 1873.

BOOKS AND PAMPHLETS RECEIVED.

Diseases of the Urinary Organs; including Stricture of the Urethra, Affections of the Prostate, and Stone in the Bladder. By John W. S. Gouley, M.D., etc., etc. With one hundred and three Wood Engravings. 8vo, pp. 368. New York, William Wood & Co., 1873.

The Science and Art of Surgery: being a Treatise on Surgical Injuries, Diseases, and Operations. By John Eric Erichsen, Senior Surgeon to University College Hospital, etc., etc. A New Edition, Enlarged and carefully Revised by the Author. Illustrated by upwards of seven hundred Engravings on Wood. 2 vols. 8vo, pp. 781, 918. Philadelphia, Henry C. Lea, 1873.

Lessons in Elementary Anatomy. By St. George Mivart, F.R.S., etc. 18mo, pp. 535. London, MacMillan & Co., 1873.

Manual of Chemical Analysis as applied to the Examination of Medicinal Chemicals. A Guide for the Determination of their Identity and Quality, and for the Detection of Impurities and Adulterations; for the use of Pharmaceutists, Physicians, Druggists, and Manufacturing Chemists, and of Pharmaceutical and Medical Students. By Frederick Hoffmann, Ph.D. 8vo, pp. 393. New York, D. Appleton & Co., 1873.

The Treatment of Whooping-Cough with Quinine. By B. F. Dawson, M.D., etc. (Reprint from the *Am. Jour. of Obstetrics and Diseases of Women and Children*, for February, 1873). 8vo, pp. 14. New York, William Wood & Co., 1873.

SATURDAY, MARCH 29, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

LECTURE V.

(Continued from page 387.)

THE mucous membrane of the larynx and pharynx is often observed, in cases of chronic laryngitis accompanying phthisis, to have a decidedly anæmic appearance. It is also frequently seen in a swollen condition, with here and there irregular elevations of a red color,—patches that have been denuded of their epithelial covering. These appearances are generally seen upon the capituli Santorinii at the points where they press together during phonation and deglutition; but the locality almost invariably and even characteristically affected is the inter-arytænoidal fold, which is usually red, often with irregular projections in its laryngeal face that assume the appearance of small warts or vegetations during the progress of the disease. This locality—the laryngeal face of the meso-arytænoidal fold—is, when the seat of disease, almost constantly covered by a layer of mucus or pus; and occasionally, when wiped clean with a sponge, discloses an irregular ulceration of the membrane, whose œdematous, notched margins constitute the vegetations already alluded to.

The vocal cords are often intensely congested, so that they are as deep in color as the general laryngeal mucous membrane, and, should the latter be at all anæmic, even of a deeper red. Sometimes they are overlaid with enlarged vessels, and sometimes studded with points of ecchymosis. Occasionally similar distinct evidences of extravasation of blood will be found upon the lateral walls of the larynx; sometimes along the anterior wall of the trachea, even to its bifurcation.

In the more advanced stages of the affection, the mucous membrane undergoes erosion, and ulcers are formed, varying in shape and position. Sometimes the ulceration is confined to the posterior laryngeal wall, to one or both ventricular bands, to one or both ary-epiglottic folds, or to some other special structure; but, as a rule, the ulcers are apt to be produced at several localities, either simultaneously or in more or less rapid succession. The vocal cords also, sooner or later, undergo ulceration, and then their free margins present an irregularly jagged or toothed outline. The posterior portion of the cord is the site by far the most frequently affected. Sometimes the ventricular band becomes adherent to the vocal cord beneath it, obliterating the ventricle; with this condition, or independently of it, one vocal cord is seen raised higher than its fellow, preventing their proper approximation, and producing persistent dysphonia. The general signs of inflammation in the larynx increase; the epiglottis is invaded, its edges as well as its laryngeal surface becoming indurated or ulcerated. The outer surface of the larynx becomes implicated, the pyramidal sinuses and the valleculæ are next affected, and the swollen structures become more and more irregular and deformed in outline, so that it is extremely difficult to describe or depict the altered appearances of the parts.

Irregular granulations are apt to spring up about the bases of the ulcerations, often forming, according to the lecturer, veritable neoplasms, which show a marked tendency to repullulation, when removed for the relief of dyspnœa, and of tickling sensations that excite irrepressible cough. These vegetations may occur upon any part of the larynx, but are found most frequently upon the inner surface of the inter-arytænoid fold. The ulcerations are often mouths of sinuses leading from the diseased or dead cartilage, and are sometimes covered by fungus-like excrescences, analogous to those observed in the skin in the neighborhood of dead bone.

Ulcerative action, when once set up in the laryngitis of phthisis, is exceedingly difficult to control. It is apt to extend to the posterior laryngeal wall and the pharynx, and there gives rise to such impediments to deglutition that the patient is no longer able to swallow his food, and has to be nourished by the rectum. Necrosis and discharge of the laryngeal cartilages are apt to follow, if the patient survives long enough for the necessary changes to take place.

Phthisis, attended with the laryngeal complications just enumerated, is apt to be chronic in its character, continuing for a number of years; and is generally attended finally with ulceration of the trachea,—ulceration that may lead to perforation into the œsophagus.

The pain in the parts is not usually very great, nor is it severe upon external manipulation of the larynx, except the posterior wall be prominently invaded, when the lateral motion of the larynx will be very painful. In some cases, however, the pain is exceedingly severe, not, apparently, from the amount of ulcerative action going on, but rather from exposure, by the ulceration, of some nervous filaments.

These laryngeal ulcerations may make their appearance before the lung-trouble has progressed sufficiently to render its existence demonstrable by physical exploration; and, on the other hand, many cases of pulmonary tuberculosis proceed to their fatal issue without any involvement of the larynx; but in the vast majority of the cases the larynx becomes involved towards the latter stages of the disease.

Local treatment of the larynx and trachea, by means of inhalations, injections, or insufflations, is generally of benefit to the patient in the laryngitis of phthisis, though often inadequate to cure the disease. Sooner or later there is an involvement of

the cartilages, in the form of a chondritis or a perichondritis, generally resulting from extension of the diseased action previously going on in the soft tissues. This is the "laryngeal phthisis" of the earlier authorities. The arytænoid cartilages are more frequently thus affected than any of the others; and, impairing the movements of the vocal cords, there is necessarily always more or less aphonia present. The cricoid cartilage is not unfrequently secondarily affected from extension of the disease affecting the arytænoids. This condition is recognized, on laryngoscopic examination, by the œdematous swelling around some point of ulceration in the interarytænoid fold, or in the parts beneath the glottis.

Sometimes the disease extends to the anterior perichondrium of the thyroid cartilage, and thence to the subcutaneous tissues, forming an abscess which may give rise to a fistula. Schrötter* narrates a case of laryngeal perichondritis without ulceration, in a tuberculous child ten years of age, which was soon followed by subcutaneous emphysema of the side of the neck, and, at a later date, by pleuritic exudation on the same side of the body.

When the epiglottis becomes the seat of perichondritis, it is converted into a thick fungus-like mass, almost always preventing a satisfactory view into the larynx. Sometimes it is the only cartilage attacked; but more frequently the arytænoid cartilages, or at least those of Santorini, are also diseased.

Perichondritis is attended usually with all the symptoms and changes of chronic laryngeal œdema. The diagnosis of this condition can usually be confirmed by the pain and tenderness produced when external pressure is made upon the larynx. The process of exfoliation of the necrosed cartilage is usually a very painful one, on account of the pressure of the sharp edges of the cartilage upon the inflamed superposed membrane, provoking frequent spasms of cough from the almost constant titillation of the parts, and often producing great pain upon swallowing. At this time it is well to nourish the patient by enemata, containing wine and quinine to sustain the strength, and anodyne enough to keep up a state of somnolency and thus lessen suffering. Ice can be kept in the mouth to allay thirst, which may also be partially allayed by frequent sponging of the entire cutaneous surface; and anodyne inhalations may be employed to soothe the inflamed tissues by their local influence.

If the necrosed cartilage can be recognized in the mirror, its progress towards detachment can sometimes be assisted with the laryngeal forceps. Such violent dyspnœa may result when the exfoliated cartilage becomes impacted in the glottis, that tracheotomy may have to be resorted to without delay. Great improvement in the local and general symptoms follows the discharge of the cartilage. Usually, however, the disease is inevitably and progressively fatal; and, after death, evidences are found of extensive participation in the disease on the part of the rings of the trachea, some of which may have even been detached and expectorated during life.

* Jahresbericht, Wien, 1871, p. 60.

THE CHRONIC LARYNGITIS OF SYPHILIS.

This affection, as seen with the laryngoscope, cannot be distinguished with certainty from other forms of chronic laryngitis. The history of the case, and the evidences of analogous disease in other parts of the body, must be taken into consideration in forming a diagnosis. The general appearances of chronic laryngitis having been mentioned in the preceding portion of the lecture, a few special points only remain to be considered. The ulcerations that accompany tertiary syphilis may attack any and every portion of the larynx, and are usually round in outline, with undermined edges, and covered with grayish-yellow deposit; features which may almost always be regarded as characteristic. The presence of cicatrization marking the presence of former ulcers is almost presumptive evidence of syphilis, inasmuch as ulcerations of the larynx rarely heal during the active progress of tuberculosis or carcinoma. The swelling of the tissues in the neighborhood of these ulcerations is apt to be of firmer consistence, or more indurated, than the swellings observed in tuberculosis, and there is not apt to be so abundant a secretion of mucus or pus as there is in the latter affection.

Syphilitic laryngitis is also usually accompanied, in its later manifestations, with syphilitic inflammation of the hard and soft tissues of the palate and pharynx, often leading to necrosis and discharge of portions of the underlying bony structure. The specific ulceration extends deeply and widely; causing such extensive destruction of the cartilages, and the denudation of such large surfaces, that in the cicatrization of the tissues the calibre of the laryngeal cavity is considerably diminished, often to such an extent as to demand the operation of tracheotomy merely for the relief of the dyspnœa produced by the stenosis. When the ulceration extends into the cartilage, this structure becomes necrosed and detached from its connections, and is apt to be coughed up; but if it be situated beneath the glottis, it may induce paroxysms of suffocation, or actual asphyxia, from its presence as a foreign body. The arytænoid and cricoid cartilages are those which are most apt to produce this complication, though occasionally it is effected by exfoliation of part of the thyroid. The epiglottis is almost invariably involved; frequently it is entirely destroyed, leaving a mere stump to represent the organ. This condition does not prevent deglutition, and sometimes does not even interfere with it.

Syphilitic chondritis, or perichondritis, which follows the specific ulceration of the mucous membrane, produces more or less infiltration in the adjacent sub-mucous tissue, presenting a condition which may be regarded as chronic œdema, and may necessitate tracheotomy. The trachea is also often involved; many of its cartilaginous rings are necrosed and expectorated; extensive ulcers are formed, the cicatrization of which produces constriction or stenosis of the tube, which, when low down, can

rarely be relieved, even by the performance of tracheotomy.

Frequently several ulcers will be seen occupying different parts of the larynx; they are rarely confined to one side, and are often symmetrically arranged upon the two sides; thus presenting a marked contrast to the ulcerations accompanying the laryngitis of phthisis. The sub-mucous infiltrations are sometimes developed into a dense fibrous tissue incapable of undergoing absorption; thus eventuating in permanent deformity and constriction of the larynx.

The vocal cords may become adherent to one another, or may be united by a broad fibrinous membrane stretching between them; dyspnœa and more or less complete dysphonia, or even aphonia, will be induced by this condition. Various laryngoscopic operations have been resorted to, for the relief of this condition, by division of the adhesions, but they have often been attended with failure, on account of the great tendency to re-cicatrization and consequent reproduction of the condition. Under circumstances of this character, it would appear proper to open the larynx externally, by division of the thyroid cartilage, and to excise the whole of the cicatricial tissue.

THE TREATMENT OF CHRONIC LARYNGITIS.

The treatment of chronic laryngitis demands, in addition to the application of local remedies, that the condition of the system be improved by a due attention to diet, clothing, exposure, and a proper maintenance of the functions of the skin and other emunctories. The local remedies may be inhaled in the form of spray, in weak solution, or, better still, may be applied directly to the parts in strong solution, by the laryngeal douche, or by the brush or sponge. When there is an excess of secretion, astringent inhalations are applicable several times during the course of the day. Alum or tannin, five to ten grains; sulphate of zinc or copper, two grains and upwards to the ounce; acetate of lead or carbolic acid in similar proportion; the sesquichlorate of iron, in very weak solution, are the most efficient of the many therapeutical remedies employed as astringents. When the parts are dry, and it is desirable to increase the secretions of the mucous membrane, the most useful applications will be found to be muriate of ammonia, five grains and upwards to the ounce; chloride or iodide of potassium, in similar proportion; or the compound solution of iodine and iodide of potassium, two or three drops to the ounce. To these inhalations small quantities of narcotics, such as the watery extracts of opium, hyoscyamus, etc., may be added if there is severe pain in the parts.

Local treatment of this kind is adequate only to the milder forms of the affection; and more potent remedies should at once be topically applied in cases of long standing or of great severity. Nitrate of silver and sulphate of zinc in ordinary cases of chronic laryngitis, tannin in cases associated with phthisis, and the acid nitrate of mercury in syphilitic cases, are the local remedies that have been found the most beneficial. The strength of the solution of nitrate of silver employed varies from forty grains to the ounce up to one hundred and twenty, and occasionally a saturated solution is employed. The tolerance of the parts, and the amount of reaction manifested, must be the guides as to the strength of the solution that is to be employed. It will be found better to make a decided impression by a severe application, and wait several days for its effects to subside before renewing it, than to torment the inflamed structures by the daily application of mild, and consequently too often inefficient, solutions. Twenty to thirty grains of sulphate of zinc to the ounce is the strength generally employed, and it is best applied by means of the laryngeal douche or syringe; while the sponge or brush should be used in making applications of nitrate of silver.

Local applications can often be advantageously made in the form of powders. Alum, tannin, nitrate of silver, and other remedies, are often used in this way, a little morphia being added when indicated for the relief of pain or cough. Scarification and more active local treatment are demanded in ulcerative laryngitis, especially when attended with a severe inflammatory or œdematous condition of the epiglottis and the upper parts of the larynx. This occurs chiefly in phthisis, sometimes in syphilis, occasionally in simple chronic laryngitis. The local use of sweet oil in this condition will sometimes alleviate the painful deglutition; and Dr. Gibb advises the similar use of a strong solution of bromide of ammonium (in glycerine), as well as its internal administration. Powder of morphia diluted with some innocuous material, as gum arabic, sugar, or lycopodium, when applied to the ulcerations, acts very beneficially. Sugar, when applied as a diluent, sometimes increases the suffering for a time; though it does seem, at times, to exert a good influence upon the ulcerative action. These applications should be repeated several times a day, according to the nature of the effects produced, care being taken that an application be made within an hour of each mealtime, so that advantage can be taken of their soothing effect upon the parts for the introduction of nourishment.

The same local treatment will be found applicable in the chronic laryngitis of phthisis. Although not always by any means curative, yet it is almost always indispensable as a means of relief, in conjunction with the constitutional treatment, which must be mainly hygienic and tonic. Tracheotomy has been recommended for the purpose of securing rest to the inflamed and ulcerated larynx; and such a result has sometimes been obtained. It cannot, however, be curative, directly or indirectly; and should be only resorted to when there is danger from asphyxia resulting from œdema or the impaction of a necrosed cartilage.

The treatment of syphilitic laryngitis in its secondary catarrhal or ulcerative manifestations does not differ from that of ordinary laryngitis. In the tertiary forms of syphilis, however, the disease can

only be arrested by specific treatment, which, in the lecturer's hands, consists usually in the local application of diluted acid nitrate of mercury, and the internal use of iodide of potassium and bichloride of mercury. The constrictions of the laryngeal cavity produced by the cicatrices of large ulcers, and the adhesions between adjoining surfaces, often exist to such a degree as to render tracheotomy and the permanent wearing of a tube necessary.

CLINICAL LECTURE

ON LIGATION OF THE SUBCLAVIAN ARTERY.

OPERATION PERFORMED AT THE JEFFERSON MEDICAL COLLEGE, DECEMBER 21, 1872.

BY F. F. MAURY, M.D.,

One of the Surgeons to the Philadelphia Hospital, and Lecturer on Venereal and Cutaneous Diseases in the Jefferson Medical College.

Reported by FRANK WOODBURY, M.D.

GENTLEMEN,—Through the great kindness of Professor Gross, who has yielded me the remaining moments of his clinical hour, I am enabled briefly to invite your attention to a subject of unusual interest and importance. The case is one of large spontaneous aneurism of the right axillary artery, which by mechanical obstruction to the circulation has produced great œdema of the arm, with severe neuralgic pains, and whose constantly increasing size threatens the patient's life, and demands operative interference. Treatment by compression of the artery has been faithfully tried and exhausted in this case, as I shall presently describe, but without controlling the growth of the aneurism or indeed producing any appreciable effect on its walls: I am, therefore, driven as a *dernier ressort* to ligation of the subclavian artery, this course affording the only hope, although a feeble one, of saving the patient.

While he is taking the anæsthetic, I will make a few remarks on the general subject of ligation of the subclavian artery, and then proceed to give the history of this particular case, and the treatment to which it has been faithfully but ineffectually subjected for the two months just past, during which it has been in my charge at the Philadelphia Hospital.

In order to appreciate the difficulties and dangers attending the ligation of this vessel, it will be necessary briefly to recall to you its anatomy, both in regard to its position and its relations with surrounding parts. It is scarcely necessary to remind you that the subclavian arteries differ in their origin, that of the right side coming from the innominate artery, while the left springs directly from the aorta. From this varied origin the arteries, in their normal arrangement, pass upward and outward to the root of the neck, over the first rib, behind the scalenus anticus muscle, and thence downward and outward to the lower border of the first rjb, where they terminate in the axillary arteries. The subclavian arteries, therefore, are divided surgically into three parts by the scalenus anticus: first, the part internal to the muscle; second, the part which is behind it; and third, the portion external to it. The difference in the origin and course of the right and left vessels is limited to the first portion, the second and third parts being precisely alike.

Operations upon the first portion of the subclavian artery necessarily vary in their conditions, according to whether the ligature is to be applied to that of the right or the left side. The greater depth of the artery on the left side, and its close relationship with the pleura, render its ligation exceedingly difficult, and the immediate proximity of important vessels and nerves enhances the risk of the operation, and renders its ultimate success practically impossible. It has been twice performed, I believe, but in both instances unsuccessfully. In Sir Astley Cooper's case, he accidentally injured the thoracic duct, and lost his patient. The operation was afterwards performed with greater success by Dr. J. K. Rodgers, of New York, whose patient lived until the fifteenth day, when he perished from recurrent hemorrhage from the vertebral artery. Guenther, in his "Operations-lehre," has collated ten cases of ligation of this artery on the tracheal aspect of the scalenus muscle, up to 1869, with the following results:

The operation was performed for aneurism in seven of the cases, in the other three the cause was not given; seven operations were performed on the right side, and in the remaining three the location was not mentioned. A fatal result followed in seven cases, in two the result was not given, and but one case was successful. Five of the cases were men, two were women, and in three the sex was not stated.

The successful case was one performed by Warren in 1849, in which the artery was in an abnormal position; it "did not lie upon the first rib, but 1" from the edge of the trapezius muscle, remote from this parallel."* This case, then, can scarcely be admitted as a precedent in estimating the results of ligation of the subclavian proper in its first portion; nor can the subsequent one of Mr. Liston's, in which he succeeded in saving his patient by tying simultaneously the common carotid and the first portion of the subclavian, for an aneurism above the clavicle. The discouraging nature of the results obtained from this operation renders it of questionable propriety,—one that should not be undertaken except as a last resort when other means have failed.

When a large aneurism forces the clavicle upward, and involves the third portion of the subclavian so as to render impracticable the ligation of this part of the artery, it has been recommended to tie the vessel behind the muscle. In order to reach the second portion it is necessary to divide the scalenus anticus muscle, upon which rests the phrenic nerve, and along whose inner border lies the jugular vein, while the pleura is in close proximity. In addition to these difficulties, the danger is enhanced by the origin of its larger branches, which arise immediately internal to this point; altogether rendering

---

* Guenther, *op. cit.*

the operation upon this portion one to be avoided. Dr. Thomas G. Morton, of this city, ligated the left subclavian between the scaleni muscles; he was afterwards obliged to amputate at the shoulder on account of gangrene of the arm, from which, however, the patient finally made a good recovery.

When the choice is offered to the surgeon, the third portion is always chosen for ligation, on account of its being comparatively superficial, and farthest from the origin of the great branches. There are a number of cases on record in which the artery has been successfully tied in this situation, generally for the treatment of aneurism; operations on the right side giving, on the average, slightly better results than the left. The first recorded ligation of the subclavian artery for axillary aneurism, in this country, was performed at the Philadelphia Hospital by Dr. Gibson, who lost his patient on the fifth day; the first case in which it was successfully performed occurred in the practice of Dr. Post, of New York, in 1817. Afterwards, the late Mr. Syme, of Edinburgh, cut open an axillary aneurism, turned out its contents, and tied both ends of the artery; he was afterwards obliged to amputate at the shoulder, on account of gangrene of the arm, but succeeded in saving his patient. Desault records two cases, both unsuccessful. After the operation, patients generally die of pleuritis, pneumonia, hemorrhage, pericarditis, shock, pyemia, or gangrene. Of twenty-one cases, tabulated by Mr. Poland, of ligation of this vessel in its second or third portion, there were nine recoveries and twelve deaths. In the successful cases, three were subclavian and six subclavio-axillary aneurisms, and in none of them did the size of the tumor exceed that of a hen's egg. The fatal cases were all subclavio-axillary aneurisms, eight of which perished from hemorrhage.* Prof. Gross, in 1841, collated twenty-seven cases of axillary aneurism for which the subclavian artery was tied; seventeen of the operations being followed by recovery. In three of the cases the artery was tied in its first portion, all of which terminated fatally. The operation of ligation of the third division of the artery, although it has given more favorable results than either of its other portions, is still attended by a high rate of mortality, and, when determined upon, the patient should be apprised of the character of the undertaking, and be carefully prepared for it physically. Our patient is fully aware of the nature of the case, but still insists on the operation; by my advice he has settled all his affairs, and has come here prepared either for an unfavorable termination or to stay until he is discharged cured.

This man is fifty-two years of age, and was born in Germany, but is now a resident of Williamsport, in this State, where he has a family. For a number of years he has commanded a canal-boat, and, living in the open air, his health has been always good, with the exception of an occasional attack of rheumatism. About eight years ago, a spontaneous aneurism formed at the lowest portion of the femoral artery. Coming to the Pennsylvania Hospital for treatment, the artery was ligated at about the middle of the thigh, by Dr. Hewson. Secondary hemorrhage followed, but was promptly controlled, and he recovered without subsequent trouble.

About ten months ago, towards the latter part of February, he experienced pain and swelling in the front of his chest and right shoulder, which he considered rheumatic; this was accompanied by neuralgic pains shooting down the arm, especially along the distribution of the ulnar nerve. In August last, a tumor was first noticed in front of the axilla, which brought him to the hospital. I then found a circumscribed tumor under the clavicle, which was evidently aneurismal, and was then about the size of a hen's egg. I decided to defer treatment on account of the hot weather, and told him to return two months later. When he came back to the hospital his general condition was much the same as before, except that he had lost all use of his right arm, which was very œdematous, and painful when moved; the tumor had doubled in size, was forcing up the clavicle, and had extended into the axilla. Being averse to ligation of this vessel, on account of its risk to the patient, I resolved that before resorting to it I would give the virtues of compression a thorough trial; by which I hoped a successful result might be attained with much less danger.

Compression of the axillary artery, in consequence of its being imbedded in soft structures, has not been found either available or effective; but the subclavian is much more accessible; where it passes over the first rib it may easily be controlled even by pressure with the finger, so as to stop pulsation in the tumor and in the radial artery. It then occurred to me that if an apparatus could be constructed so as to compress the artery in this situation for a few hours at a time through a number of days, avoiding on the one hand the brachial plexus of nerves, and on the other the subclavian vein, a temporary stasis of the blood might be established, followed by the internal deposit of fibrin on the walls of the tumor, and gradual obliteration of its cavity, thus curing the aneurism. By this means we would avoid the danger of gangrene of the sac, which would almost certainly follow sudden complete coagulation of the blood in the tumor, and the subsequent suppuration, and probable pyemia. Acting upon this, I devised an apparatus, which Mr. Gemrig made for me, consisting essentially of a steel buckskin-covered bow, passing over the shoulder, containing a small tourniquet to screw down upon the artery; this was fastened front and back to a padded perineal band, and to a broad band of webbing going around the chest, to secure it all in position. The tourniquet was made freely movable in the antero-posterior plane, so that it might not be displaced in the involuntary motions of the body, as in respiration; it could, however, be fixed in position at any inclination by means of a slot and screw.

The details of this case are interesting, as it is the first case recorded in this country, to my knowledge, where systematic compression of this artery

* Quoted from Gross's System of Surgery, fifth edition.

has been resorted to for the cure of axillary aneurism.

Before the apparatus was completed, the artery was compressed upon the first rib by a tourniquet with a handle, which was held in position by an assistant, with the following result:

October 23.—Compression was kept up for five hours, the patient being fully anæsthetized with Squibb's stronger ether during the process. Some difficulty was experienced in commanding the current of blood through the vessel, slight movements being sufficient to throw the compress from the artery. During the operation the aneurism became quite small and firm, retreating into the axillary space, but when the pressure was removed no marked improvement was noticed.

October 31.—The patient was again anæsthetized, and the pressure maintained for five and a quarter hours. The tumor appeared somewhat smaller and did not pulsate so strongly after these two sittings; during which the brachial artery was controlled by the fingers of an assistant, thus combining the advantages of the Hunterian operation and Brasdor's. After both occasions the patient suffered severe pain darting down the arm, coming on in paroxysms, generally early in the evening, for several days. This was controlled by large doses of morphia, and anæsthetics. Tincture of aconite was given in sufficient doses to reduce the pulse.

The apparatus was completed on the 20th of November, and applied in the presence of Prof. Gross and my colleagues at the Philadelphia Hospital. Prof. Gross gave as his opinion that ligation would be the only effective treatment, but acknowledged, with the others present, that the circulation in the tumor and radial artery was perfectly controlled by the apparatus. Dr. H. C. Wood, Jr., after auscultation, pronounced the aorta probably atheromatous. The existence of such a condition of the vessels I had already suspected, from the fact of this being the second spontaneous aneurism, and this disease of the arteries made me regard ligation with still less favor.

A slight alteration being required in the apparatus, compression was not regularly instituted until a week later. The following record of the treatment is kindly furnished by Dr. E. W. Stone, my resident physician; the patient during the compression being in the sitting position, and not under the influence of ether:

November 27.—The improved apparatus was applied, and pressure kept up one hour. Half a grain of morphia was given hypodermically.

November 28.—Pressure applied for three-quarters of an hour.

November 29.—Applied for one hour and five minutes.

November 30.—Pressed for one hour and twenty-five minutes.

December 1.—Pressure taken off after fifty minutes.

December 2.—Pulsations controlled for one hour and fifty-five minutes.

December 3.—Artery compressed for two hours and ten minutes.

December 4.—Apparatus applied for three-quarters of an hour in the afternoon, one hour in the evening.

December 5.—Controlled for two hours and fifteen minutes.

December 6.—Pressure for one hour.

December 7.—Pressure maintained for two hours.

December 9.—Apparatus kept on for three hours and five minutes.

December 10.—Two and three-quarter hours in the morning, three hours in afternoon, one hour in evening.

December 11.—Four hours in morning, one hour and fifteen minutes in afternoon.

December 12.—Compressed for one hour and thirty minutes.

December 14.—Compressed for two hours and thirty minutes.

December 15.—One hour and five minutes.

During these sittings morphia was used hypodermically,—one grain being generally given in two doses. This was usually sufficient to control pain and inconvenience from the pressure of the tourniquet; but when neuralgic pain in the arm set in the pressure always had to be removed, the morphia being of no avail to prevent it. It was found that as the parts over the clavicle became quite tender in a few days, the artery could be much more readily controlled by shifting the pad of the tourniquet inward towards the median line and directing it backward against the transverse processes of the cervical vertebræ. While this pressure was being carried on, much of the œdema in the arm disappeared, and the arm itself became more tolerant of manipulation; the tumor became somewhat more consistent, and did not pulsate so strongly.

Treatment by compression has been faithfully tried in this case without accomplishing the cure of the aneurism, and the pressure finally caused such neuralgia along the nerve-trunks of the arm and hand that we were obliged to desist. The impulse of the tumor has slightly diminished, while its resistance to pressure has increased, showing some thickening of its walls. In connection with compression I have thought of electro-puncture, or the injection of a few drops of the perchloride of iron; but, as they would produce immediate coagulation of the blood and thus subject the patient to the dangers of gangrene of the clot and pyemia, I think that ligation of the subclavian artery would give the patient the better chance for his life. I adopt this course more confidently because it meets the approval of such distinguished gentlemen as Professors Gross and Pancoast, who are present to assist at the operation, and Drs. Packard, Brinton, Pancoast, Allen, and others.

I will not detain you with an account of the details of the operation, but will merely state that I will first make a transverse incision through the skin and platysma myoid, along the upper border of the clavicle. Reflecting back the flaps, the field of operation is before me, with plenty of room for the subsequent steps of the operation. Reaching the artery, a curved aneurism-needle is passed under it, from before backwards, and the artery secured with a silk ligature. The vein was not injured, and the wound is brought partly together, and cold-water dressing applied. The operation itself, thus far, is perfectly successful; the patient will be kept absolutely at rest in the horizontal position, and be supported with a light but nourishing diet. We have given the patient the only chance for his life

in our power, and now can but hope for the best result from our endeavors.

Saturday, January 5, 1873.—Dr. Maury came before the clinical class to announce the unfavorable termination of the case, exhibit the post-mortem results, and relate the progress of the patient after the operation.

December 21, 1872.—Half an hour after the operation, he appeared to be suffering no pain, and the pulse was 78. During the evening he felt well and was very talkative, but had some occasional pain in the tumor. He woke in the night, after sleeping soundly, complaining of intense pain, for which he had a half-grain of morphia, which relieved him, and he fell asleep again.

December 22.—After a good night's sleep, he woke complaining of pain and cramps in the arm, which were controlled by one-third of a grain of morphia. Three hours later there was no pain and no pulsation in the tumor. Pulse 80.

December 23.—Slept well; took one and a twelfth grain of morphia through the day to relieve pain and restlessness. Appetite fair; no fever; skin moist. Pulse 84.

December 24, 25, 26.—Still doing well, and appetite improving. Severe pain at times, controlled by an anodyne. On the evening of the 26th, pulsation in the radial artery was detected. Pulse 88.

December 27 and 28.—Doing well, but suffering, at times, intense pain; he said that otherwise he felt well, and ate with a good appetite.

December 29.—He slept well all night without morphia. He ate a very hearty dinner, and in the afternoon was feverish and thirsty. Pulse 96. He complained of pain in the arm at intervals.

December 30.—He was restless during the night, and rather flighty at times. He complained of a feeling of great oppression in his chest, and the nurse had to raise him up in bed to breathe. He was thirsty and feverish, and, towards morning, sweated profusely. He ate no breakfast nor dinner, and seemed inclined to sleep. In the evening, as his bowels had not been moved since the day of the operation, a dose of castor oil was administered. This produced a large evacuation, besides making him sick at his stomach, and causing vomiting.

December 31.—He had no sleep whatever during the night, on account of pain in the wound and in the arm. He had no appetite for breakfast, and took three-quarters of a grain of morphia through the morning. At 11 A.M. he had a hemorrhage from the wound, losing about three ounces of blood. He was ordered one grain of opium, in pill, every hour, for four hours. Pulse at 2 P.M. was 116. At 2.45 P.M. he had another hemorrhage, and lost, in all, about a pint of blood. He was directed to take, every hour, five drops of tincture of aconite, until three doses were taken. The last and fatal hemorrhage gushed out in full stream, at about 8.25 P.M. This was controlled almost immediately by the fingers of the nurse, but the patient rapidly sank, and died at 11.10 P.M., on the tenth day from the operation.

The post-mortem showed the ligature in good position and just ulcerating through. The aorta and heart were in an advanced stage of fatty degeneration, and plates of calcareous deposit existed in its valves and in the walls of the aorta. The subclavian artery was in part filled with fibrinous coagulum, and partly with a soft clot, evidently more recent, from the innominate to the ligature. The hemorrhage was the cause of the fatal result in this case, and leads us to the impression that without tying, in addition, the common carotid or some of the large branches of the subclavian, the dangers of the ligation of this artery are such as to make the operation, as a rule, unsuccessful; while by simultaneously securing these vessels a probable failure may be transformed into a possible success.

ORIGINAL COMMUNICATIONS.

A CASE OF ACUTE TUBERCULAR MENINGITIS.

BY C. SEYMOUR, M.D.,
Hinsdale, Mass.

TUBERCULAR meningitis in so acute a form as was exhibited in the following case is to me a somewhat rare disease. The case, from its earliest manifestation to its close, occupied only eighteen days. There was no prodromic stage whatever, as is the common event in this disease; and no acceleration of the pulse in the earlier stages. Not a single convulsion occurred, and there was never any paralysis. In these points the case was of especial interest.

George P., æt. 11, a bright, promising boy, with black hair and eyes, and a light thin skin, complained, February 1, of frontal headache, anorexia, and general malaise. Pulse 76. For a week he manifested little alteration, with the exception of extreme peevishness of temper, an increasing disposition to be left entirely undisturbed, and a gradually decreasing pulse until it reached 52, being at the same time very irregular. He vomited once, and this was the only time during his illness. His bowels now remained constipated. Special senses of sight and hearing became morbidly acute. On the 11th he passed into the stage of delirium, which continued two days. This was followed for a day with somnolency, in which his intelligence was easily aroused, but would as easily lapse again into a peaceful slumber. This state was succeeded by the final one of coma, not profound at first, but gradually deepening, the pupils becoming dilated and unlike, and irresponsive to light, the right lid drooping, the breathing growing stertorous, the pulse now going up rapidly to 160 and higher, until death took place on the 18th. The three stages were thus well marked: the cephalalgia, the delirium, and the coma. *The pulse was not rapid at first*, but declined in the second stage, then rapidly increased in frequency in the last stage. Constipation was present, with but a single evacuation of the bowels, and that involuntarily, during the delirium.

Autopsy by Dr. J. F. A. Adams, of Pittsfield.

The meningeal vessels were found highly engorged with blood; tubercular masses in abundance were clustered upon the summit of the brain, imbedded in the pia mater; and at the base of the brain and about the fissures of Sylvius these yellow granulations were abundant, especially in the processes of the pia mater as they dipped down between the convolutions. This membrane itself was thickened, opalescent, and firmly adherent to the cerebral substance. The ventricles contained over three ounces of an amber-colored fluid.

TREATMENT OF HOOPING-COUGH. — Dr. Charles Kelly, in *The Practitioner* for March, 1873, reports some experiments with belladonna in this disease. It was given in full doses, ℥x to ʒss. of the tincture every two, three, or four hours, for four or five days at a time; and the effect seemed to be to lessen the severity and duration of the coughing-spells.

Dr. Berry, of Lancaster, is quoted in the same journal as advocating the use of dilute nitric acid, ℥v to xv, given in simple syrup every three or four hours. He thinks it not only allayed the cough and spasm, but actually cut short the disease.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 29, 1873.

EDITORIAL.

THE PARTY OF THE OTHER PART.

READERS of this journal will hardly need to be told of our earnest opposition to the whole business of diploma-selling. But, on the other hand, we are quite as much inclined to blame the buyers or would-be buyers of degrees. We will venture to say that there is not a single one of the many who have nibbled at the bait thrown out by bogus colleges, or bought their worthless wares, who did not know that in so doing he was a party to a fraud.

The makers of counterfeit money and of counterfeit diplomas would be alike innocent if they had no market upon which to throw their products, nor a public to be deceived and swindled by the uttering of them. The "coiner" must have his "shover," and the seller of the degree *in absentiâ* must have his ignorant and unqualified customer, who will trade upon the unsuspecting patients or clients who regard his title as genuine.

A recent number of the *British Medical Journal* contains a letter from one who signs himself "A Victim," and confesses that he paid £42 for two degrees, one of M.D. and one of LL.D. The editor justly declines to pity him. He ought to have known that no such proposition could be made in good faith,—that he could not get a certificate of qualification, worth the paper it was written on, without proper study and examination. It is a good thing to break down the traffic in diplomas by closing the bogus schools which issue them; it would be still better to do it, if possible, by dealing with those who are willing to become their patrons, and who are equally parties to the fraud.

MORBID CURIOSITY.

THERE are few more curious or more unpleasing psychological phenomena than the enjoyment experienced by the great mass of mankind in dwelling on the details of crime and its punishment. No novel has ever had more eager readers than the Newgate Calendar; and perhaps no book, not manifestly immoral in its principles and objects, has ever had a greater influence for evil. It was, we believe, Sir Joshua Reynolds who told one of his art-pupils never to look at a bad picture if he could help it. The tendency to unconscious imitation is too strong in the human mind, to make the study of crime, except for the direct purpose of its prevention, a safe pursuit.

We are led to these remarks by the fact that all over this country the newspapers are full of the revolting details of the crime and punishment of the wretched Foster, in New York. Thousands of young minds are probably this evening (March 21) gloating over the narrative. We do not believe that those who control these potent agencies of good or evil can realize the poisonous character of the matter they help to spread, or their responsibility for the harm so done.

LEADING ARTICLES.

LEGISLATION RESPECTING EXPERT TESTIMONY.

SENATOR WALLACE has introduced a bill into the Senate of this State for the purpose of providing reliable expert testimony in criminal trials where the defence is insanity. By this bill, parties wishing to avail themselves of this defence are obliged to give notice beforehand to the court, which then appoints a commission composed of two physicians and one lawyer, who are to make thorough inquisition of the case. Their conclusions respecting the mental condition of the party, unaccompanied by note or comment, are to be transmitted to the court, and given to the court and jury as "persuasive evidence" in the subsequent trial, in which, however, the prisoner is not debarred from calling such other expert witnesses as he chooses.

It passes our comprehension to see what would be

gained by this proceeding, except to substitute two trials for one, with double cost and trouble. None of the familiar objections against expert testimony as received at present would be obviated; because, if we rightly understand the bill, the jury trial is to suffer no change from the ordinary mode of procedure. The prisoner may call any number of witnesses, skilled or unskilled, competent or incompetent, paid or unpaid for their opinion, to prove insanity. Neither would anything be *settled* by the commission. They are obliged to testify at the trial and give reasons for their opinion, precisely as if it had not been already used as "persuasive evidence;" they may be badgered by counsel bent on making the worse appear the better reason, and forced to contradict themselves by an artful juggle of hypothetical cases or some paltry shuffling of ordinary facts. The only conceivable benefit to be obtained from this commission would be that of getting two expert witnesses free from the bias produced by being employed and paid by the prisoner, the bias on the other side remaining as strong as ever. We are not disposed to undervalue this benefit, but it would be so far outweighed by other considerations as to be, in practice, of comparatively little account. What is wanted above all things else is real skill; and that is no more likely to be furnished by the court than by the parties in the case.

Then, too, it is to be considered that the members of the commission may not agree in their conclusions. One may find the prisoner quite crazy and devoid of responsibility; another may regard him as only partially insane, and more or less responsible; while the third may believe that the apparent insanity is nothing more than a form of depravity. By what contrivance of examination-in-chief and cross-examination on the trial, these several opinions are to be attacked and defended, is not very obvious. But it is very clear that such discrepancy can be scarcely less damaging to the cause of justice, than those discrepancies which are so much complained of now.

The manner in which the commission is to be compensated for their services would greatly hinder the successful working of even a better provision than this. The court is directed to fix the compensation according to its own discretion, for no rate is prescribed. It needs little worldly wisdom to predict as a consequence of such an arrangement any amount of disappointment and dissatisfaction. The value of men's services, generally speaking, is not always estimated alike by employer and employed; and in the case of scientific service like this, the diversity of estimate may be of the widest kind. If the court were guided by the measure of its own salaries, we are inclined to think it would seldom have the opportunity to employ men fully competent for the purpose, and whose conclusions would be satisfactory to the public. To prevent any uncertainty on this point, we must suppose a bargain to be made beforehand, and that also supposes a scene of dickering between the court and the expert, not calculated to exalt our notions of judicial dignity. The tendency of this provision, obviously, is to put into such commissions persons of inferior attainments, while the prisoner and his friends might spare no expense in securing the services of experts of the highest reputation in their profession. The State need not expect to obtain men for this purpose, of acknowledged competence, unless it is willing to pay them somewhat according to their own notions of what they are worth.

We regret to be obliged to throw cold water on any well-meaning attempt, as we sincerely believe Senator Wallace's is, to remove the impediments to a satisfactory administration of justice in the class of cases in question, but we strongly doubt if true reform lies in that direction. With no disposition to underrate the real delinquencies of experts, we insist that much that passes for such is but the unavoidable and legitimate result of scientific inquiry. When scientific men shall be conducted to their conclusions by some sort of miraculous endowment, they will undoubtedly all agree, and their utterances will be infallible; but until then we shall doubt the wisdom, if not the practicability, of any mode of procedure that necessarily prevents disagreement. "'Tis true, and pity 'tis 'tis true," that men not unfrequently thrust themselves as experts upon the witness-stand who have no business there; but if our juries were constituted as they should be, little harm would come from their testimony. It is because of the well-known stupidity of juries and their lack of any sense of responsibility, that such so-called experts have presumed to inflict their presence upon our courts of justice. When we shall have ceased excusing from jury-duty almost every man tolerably competent to perform it, and putting into the jury-box men hardly knowing their right hand from their left, we shall have little occasion to complain of the delinquency of expert witnesses. If Senator Wallace and others of like intent would devise some legislation with the view of improving the character of our juries, they would do more towards relieving us of objectionable experts than they can by the most ingeniously contrived commissions.

CORRESPONDENCE.

LONDON LETTER.

[*From Our Own Correspondent.*]

The Case of the Emperor Napoleon—Clinical Lecture by Sir Henry Thompson—Hunterian Oration by Mr. Hancock—The Societies—Centenary of the Medical Society of London—The New Obstetric Journal—The London Anniversary of the British Medical Association.

LONDON, March 3, 1873.

WE have not ceased to discuss the case of Napoleon III. The somewhat provoking delay in the publication of the promised detailed account of the case by the Emperor's private attendants has indeed rather excited than dulled our interest in the subject. This delay is due, it is stated, to the absence of M. Conneau from London; but it is not altogether advantageous, as it leads to continued public criticisms without sufficient data. The graver monthly journals, such as the *Edinburgh Medical Journal* and *The Practitioner*, in their numbers just issued, discuss the case, and both condemn the treatment; but the articles bear traces of an injudicious reliance upon mere hearsay, and, indeed, contain assumptions which I have reason to know to be contrary to the fact. Both assume that the operation and treatment were guided by a conviction that the kidneys were sound, and it is roundly intimated that a knowledge of the earlier history of the case and of the consultation of MM. Nélaton, See, and Ricord was withheld from the London doctors concerned. This was not so.

In a very interesting clinical lecture delivered by Sir Henry Thompson on Saturday last at University College Hospital, he boldly discussed the subject of the influence of renal disease on the choice of operation for vesical calculus. He started by pointing out that the grounds of choice now are very different from what they were twenty years ago, and that the data most generally relied on by those who have recently written upon the subject belong rather to a by-gone period than to the present day. The statistics of mortality from lithotomy have not varied perceptibly during the last thirty years. It is quite otherwise with lithotrity. Its achievements are altogether modern, and the mortality from lithotrity in the hands of practised adepts bears no comparison with that of earlier days. An amount of kidney-disease which forbids the idea of lithotomy does not, in Sir Henry Thompson's opinion, necessarily contra-indicate lithotrity. He instanced seven recent cases in which, notwithstanding evidence of advanced disease of the kidneys of a formidable kind, he had relieved patients in the wards from the torments of calculi in the bladder. He ridiculed the idea of ascertaining the extent to which the ureters are dilated by plessimetry, as M. Piorry has suggested, and asked whether that physician would undertake by plessimetry to map out the lumbar plexus in the healthy body,—the easier achievement of the two.

The lecture was bold and honest, and, although it will no doubt excite criticism, its author will not shrink from bringing his statements to the test of clinical experience, on which, indeed, they are founded.

There is no use in shirking the fact that lithotrity in the hands of a highly-practised and thoroughly-skilled operator is a very different thing from the same proceeding in the hands of a good surgeon not thoroughly practised. Every surgeon of ordinary knowledge and capacity can lithotomize, and do it as well as another. A very small difference in skill, tact, and experience in lithotrity makes an immense difference in the results. It is painful and surprising to see how skilful surgeons "bungle" with the lithotrite, after having seen Thompson handle the instrument.

An unpleasant impression has been produced here by an oration delivered by Mr. Hancock, as Hunterian orator, at the Royal College of Surgeons. The oration was a studied denunciation of preliminary examinations in arts. No doubt occasional hardships occur in the rejection of youths who possess fair abilities but yet have failed to master an adequate knowledge of arts and letters. But there are very few indeed, however, who do not admit the necessity of a preliminary test which shall prove that aspirants for medical diplomas have the ordinary education of English gentlemen; and besides one or two of the elder school of unlettered practitioners, to which Mr. Hancock belongs, he finds no sympathizers. Mr. Hancock has, however, a *fidus Achates* in one of the subordinate officials of the college, who, to the great scandal of the profession, procured by means at his disposal the admission of a very full report of this oration in the columns of the *Times*, and so gave to an address which was really an anachronism something of a representative character. The medical press has been unanimous in its condemnation of the address, and Mr. Hancock's colleagues are by no means well pleased.

The Societies are in active operation. A very interesting case was brought lately before the Royal Medical and Chirurgical Society, in which a needle which had lodged in the heart for seven days was successfully cut down upon and removed by Mr. Callender, at St. Bartholomew's Hospital. A discussion has been opened at the Clinical Society of London on the influence of excessive exertion—such as that in which the amateur athletes of our universities and public schools indulge—upon the heart. Some very strong evidence of its injurious effects was adduced, and the whole subject is likely to be fully discussed. I will presently summarize the conclusions.

The Medical Society of London, the oldest, but of late years the least esteemed, of our medical societies, is making an effort to raise itself in the scale of scientific esteem, and not without success. It has the advantage of an ancient foundation and of endowed funds: nevertheless, until lately it has been the resort chiefly of third-rate talents and of the demi-monde of medical science. It has been a good deal improved by the efforts of such men as Dr. Andrew Clark, Dr. Richardson, and Dr. Habershon, and it is about to celebrate its

centenary by going into new and handsome premises, establishing printed proceedings, and other measures which indicate revived prosperity. It is never likely, however, to rise much above the fifth or sixth place among the London societies.

A new monthly journal, *The Obstetric Journal*, is announced to appear on the 1st of April. It will be edited by Dr. Aveling and sub-edited by Dr. Wiltshire,—the one a provincial practitioner of ability and energy, who has recently come to London, and the other a very energetic and hard-working young man, who is aiming with earnestness at a high place in the ranks of obstetric medicine. The prospects of this journal are considered very doubtful; but it is tolerably sure to deserve success, if it cannot command it. All the journals give a great deal of obstetric matter: three societies—the London, Edinburgh, and Obstetrical Societies—publish volumes of transactions; the *British and Foreign Medico-Chirurgical Review* and the London *Medical Record* give full obstetrical summaries: so that it is not clear whence the body of subscribers likely to support a new special journal of the kind are to come. On the other hand, the subject is one of vast interest to the great mass of practitioners, and there is little doubt that the new journal will contain good and instructive matter.

The British Medical Association will hold its annual meeting this year in London; and the occasion is likely to be one of great interest. Its former London meeting was held ten years ago, when the Association numbered less than one-half of its present roll—upwards of five thousand members—and enjoyed far less prestige. Sir William Fergusson will preside, and probably not fewer than eight hundred or nine hundred members will attend. A very influential Reception Committtee has just been formed, and money is flowing in to provide a handsome reception in return for the large liberality which the great provincial and university towns have shown of late years at the successive annual meetings in Dublin, Cambridge, Oxford, Leeds, and elsewhere. A great number of distinguished foreigners will attend, and I hope that among them we shall see a large proportion of your countrymen. They are always sure to be most cordially welcomed if they take proper means to make themselves known. The meetings will be held on the 6th, 7th, and 8th of August.

THE "BIDDING" AT WHEELING, W. VA.

To the Editor of the Philadelphia Medical Times:

DEAR SIR,—I have read with much regret your editorial remarks in the *Times* of Saturday the 8th instant concerning "a remarkable transaction" published in a recent number of the *Wheeling Daily Intelligencer*, which, you say, was handed you "by a friend."

If I were not sensible of the value of your good opinion, and sufficiently mindful also of the influence of the *Times* with the very best men of the profession in all parts of the country, I should not trouble you with this note in explanation of the "Curious Inconsistency" you have recorded.

I cannot help believing that newspaper was sent from Wheeling to your Philadelphia friend for the unjust and unmanly purpose of leading him, if possible, and others into a participation of the prejudice of the *sender* against one of "the two gentlemen" to whom you have referred as having offered their professional service to Ohio County at poor pay, "in the face of their own remonstrance against the very proposal to them so to underbid one another."

Fearing some such discourteous use of the paper containing the proceedings of the County Commissioners, I sent to the editors of the *Intelligencer* the following communication, which, if an excuse to misrepresent me had not been sought, should have followed quickly the previous day's paper to your friend:

"Wheeling, February 4, 1873.

"To the Editors of the Intelligencer.

"In your report of the proceedings of the County Commissioners in session yesterday, I am so much misrepresented that I cannot suffer the publication to pass without calling your attention to the awkward and erroneous position in which you have accidentally placed me.

"1. I sent in *no bid* to 'render medical and surgical attendance to the poor, including service at the jail to county prisoners, the examination of lunatics, and conduct *post-mortem* examinations,' in answer to an advertisement for proposals for such service, bearing date the 15th of January.

"2. I was *not* a candidate for the new office created and filled yesterday to supply the above-named public service at the pay of $500 per annum.

"For more than two years I have been serving the poor within the city limits by special contract with the late Board of Supervisors. That contract expired January 1, and I sent to the Clerk of the Board the following note, several days prior to the meeting of the Commissioners when the advertisement for proposals, etc., was authorized to be published:

"'Wheeling, January 6, 1873.

"'*Charles B. Cecil, Clerk County Commissioners:*

"'Dear Sir,—There being no provision since January 1 (when my contract expired) for medical service to the poor within the city limits, I have not discontinued my attentions to several needy patients who are still on hand. In other words, I shall continue my services to the sick poor until otherwise instructed by the proper authorities. Should the new Board of Commissioners desire to renew my former contract, I am willing to accept its terms for another year,—that is, $350 for service to the poor within the city limits. If not for the year, I am sure they will not object to *paying me* for service rendered until my successor is appointed.'

"Very respectfully,

"James E. Reeves."

My contract was to supply simply medical and surgical attendance to the poor, "on the order of an overseer of the poor or member of the Board of Supervisors." This contract I proposed to renew for the reasons stated; and my proposition antedates the advertisement for proposals for the joint service to the poor, to the jail, etc., etc.; and hence it was in no wise a *bid;* nor did this letter authorize the use of my name as a candidate when the new office was filled.

"Why the Board advertised for bids" can be easily answered. At the January meeting of the Commissioners it was discovered that my contract had expired; but, for some reason, my letter as above, addressed to the clerk, was not read. At this point in their proceedings a proposition was received from Dr. Bates, Jr., to continue the service I had been performing at the same rate of pay, $350 per annum; but it was rejected, and a resolution carried to advertise for bids not only for "attendance on the poor," but for the additional service of "examinations of lunatics, and post-mortem examinations in case of medico-legal investigations, to be awarded to the lowest bidder by the year."

The next day after these proceedings, I met two of the Commissioners, and assured them that no physician in good standing would *bid* for the service proposed; that if the action of the Board was adhered to, the result would be, the duties required would surely fall into *irregular* and incompetent hands.

After this conversation with those gentlemen, it was agreed by the committee having the matter in charge to propose an ordinance prescribing all the required duties, and have the same ready to submit at the next meeting of the Board. The salary was fixed at $500, and the ordinance, as proposed, adopted. The next thing in order was the election of the officer; and this is the way in which "one of these bidders who offered his services for $350 was actually elected to serve at a salary of $500."

In justice to the regular profession of Wheeling, it should be told that no "*bid*" from among them was made in answer to the advertisement for proposals to perform the above-described service; and that, in view of this result, the Board of Commissioners of Ohio County were induced to adopt another plan than that of selling out medical practice to the lowest bidder.

Trusting that by these lines I shall be able to disabuse your mind of the error which has been imposed upon you, I am, dear sir,

Your friend truly,

JAMES E. REEVES.

WHEELING, WEST VIRGINIA, March 10, 1873.

DR. LETHEBY ON FOOD IN AMERICA.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

EVERY one knows the high authority of Dr. Letheby; assured not only by his ability and learning, but also by his position and experience as, for a number of years, Medical Officer of Health to the City of London.

Reading with much interest the second edition of his lectures on "Food," a book especially rich in figures and facts upon that subject, I was struck with some statements in regard to this country, of which it would not be well for us to be ignorant, *if they be true*. The following are literal extracts:

"The sallow, weazen look of the natives of the Northern States of America is thought to be due to the indigestible preparations of Indian corn, called *mush*, *hominy*, or *johnny*, which constitute the chief portion of their daily meals." (P. 17.)

"In America the elaborateness of the *menu* for breakfast, dinner, and supper is very striking,—the breakfast in the large hotels being from eight to eleven, luncheon from one to three, dinner from six to eight, tea from eight to nine, and supper from ten to twelve; making ten hours a day for the disposal of most elaborate meals." (P. 135.)

"Hares which have fed upon the *Rhododendron chrysanthemum* are frequently unwholesome; the same is the case with pheasants in Pennsylvania and Philadelphia, which feed during the winter and spring on the buds of the laurel (*Kalmia latifolia*); and I have known many instances of serious mischief from prairie-birds, which are largely imported into this country from America, and I attribute it to the food made use of by the bird. In certain districts of North America, especially on the Alleghany Mountains, *the flesh of all the cattle is poisonous, and so also is the milk they yield, and the cheese which is made from it.*" (P. 221.) (The italics are ours.)

On the first of these assertions our deference to Dr. Letheby's authority cannot carry us further than to ask (for information?) three questions: "Are the natives of our Northern States, as a rule, sallow and weazen in appearance?" "If so, is this due to preparations of Indian meal?" and, lastly, "Do *mush, hominy*, or *johnny* constitute the chief portion of their daily meals?" The answers may be left to the many readers of the *Times*, as well as of Dr. Letheby's book, who live in the Northern States. Dr. Letheby's informants must have penetrated farther into the wilds of "Massachusetts and Boston" (to paraphrase one of our author's expressions) than most of us have done, to discover tribes of natives of whom either of these things is true.

About the next matter—the elaborate *menu* of all meals in America, as represented in our "large hotels"—a diffident suggestion may be made, to the effect that an average "native" scarcely ever devotes quite so much as ten hours daily to the "disposal" of his (mush and johnny?) meals. We can perhaps imagine an English gentleman, travelling at leisure, doing so. In such a case he would have to be much absorbed in his *menu* not to see that those who come in through the ten hours accomplish their meals in as short a time as the inhabitants of most other countries.

But as to the kalmia-poisoned pheasants of "Pennsylvania and Philadelphia" (adjacent States?): are our sportsmen familiar with them? Dr. Letheby, no doubt, has read Longfellow's poem of Evangeline; and there

it is told that, in our town, "the streets still re-echo the names of the trees of the forests." But it would probably be news at Augustin's or Guy's that the laurel was causing mortality at any season among their customers.

Most remarkable and important, however, is the last of Dr. Letheby's American "facts." Those cattle of the Alleghanies: are they wild or tame? Has Hayden, Leidy, or Cope yet explored those regions? We want to know. Some of us have occasionally crossed those mountains, and have even spent summer days or weeks among them; yet we have not met with the poisonous beef, veal, milk, or cheese. Are we unaccountably ignorant? Or is it just possible that Dr. Letheby may be mistaken, and even *careless*, about his *facts?*

Respectfully,
HENRY HARTSHORNE.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, March 12, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

DR. SAMUEL H. FREEMAN offered some remarks on *Laryngitis*. "This," he said, "is one of the most distressing diseases incident to humanity; but happily it is of rare occurrence, since in the greater proportion of cases in which it has occurred it has proved fatal.

"Of course slight inflammation or congestion of the surface of the mucous membrane of the larynx is not uncommon as the result of colds, induced by exposure to sudden and extreme changes of temperature, and is, in general, neither dangerous nor unmanageable; but when the inflammation affects not only the mucous membrane, but also involves the sub-mucous tissue, causing engorgement and serous effusion, or pseudo-membranous deposits, the dyspnœa and dysphagia become fearfully distressing, and the patient frequently sinks from asphyxia, unless relieved by active medication, or that *dernier ressort*, tracheotomy.

"This disease occurs almost exclusively during the early period of adult life, and usually in persons of robust habit. The treatment must be prompt and effective; and I know of no disease in which the utter impotency of homœopathic treatment is so clearly illustrated as in acute laryngitis and that class of inflammatory diseases. Cases are recorded which have terminated fatally in seven hours from the attack.

"In the treatment of a case of this distressing disease which occurred recently in my own practice, after the application of leeches and fomentations, together with the administration of slightly nauseating doses of antimony and lobelia, I made free application of the cantharidal collodion over the region of the larynx; and this seemed to prepare the way for the greatest relief which the patient experienced from the careful and persistent inhalation of the steam of boiling water.

"It is an interesting fact that the ciliated epithelium which lines the larynx, and whose functions are secretive and protective, subserves also the function of aeration, and is aided in this by the cilia preserving a proper state of moisture over every part of the membrane. These cilia, which are among the most minute objects known to the histologist, are in incessant motion; and this motion will continue many hours after death (seventy-eight hours, according to Virchow), if the cells are kept moist.

Dr. AMOS FOWLER said that he approved of the use of steam; and his plan was to fill the room with it, and in a few hours, in cases of stridulous breathing in croup, he had noticed a marked advantage from its use.

Dr. F. C. CURTIS then related the following case: A child, æt. 5 years, inhaled steam from the spout of a tea-kettle; she cried for a little while, but was readily pacified with candy, and for two or three hours did not suffer much; then the breathing became difficult and the voice hoarse.

When seen, about five hours after the accident, the face was suffused, the breathing was labored and irregular, and the voice was wanting; the pulse was rapid, and the skin hot.

By passing the finger into the throat, two tumors of the size of the end of the thumb were felt at the base of the epiglottis, showing œdema of the glottis; probably it was the same condition extending into the larynx and trachea, which produced aphonia.

On this account an operation, scarifying or tracheotomy, did not seem to offer hope of success, especially considering her low condition. Hot applications were bound around the throat and chest, and the room filled with vapor by kettles of boiling water on the stove; but the next morning she was moribund, and died twenty-four hours after the injury.

Dr. CURTIS presented in this connection a hard rubber tube with a proper curve for passing it into the trachea; this was used with success in the hands of Prof. Wiederhofer at the Children's Hospital in Vienna, in cases of true croup. After being passed through the rima glottidis, the breathing became more easy. By passing a feather through the tube, considerable false membrane was entangled and removed.

Dr. AMOS FOWLER then reported a case of *gangrene of the leg*. Mr. P., æt. 77, was naturally strong and robust, had been in the habit of using alcoholics, tobacco, and opium for twenty-five years. For the last ten years used opium and tobacco to excess.

December 20, 1872, paralysis occurred on the left side. Nothing unusual appeared in his case, excepting a great torpor of the bowels, until January, 1873, when the left foot began to swell, increasing until the last of the month, when gangrene commenced in the leg, a little above the foot. This spread slowly, involving the whole foot and the lower part of the leg. His appetite remained good, and his pulse was seventy, until the middle of February. After this his mind became dull; in a few days more he was seized with convulsions, which continued at short intervals until his death, February 20. He called for more opium as long as he could speak.

Prof. JAMES MCNAUGHTON reported a case occurring in his practice in a person æt. 40, naturally strong and of full habit, who had been subject to slight attacks of rheumatism. He first suffered from pain in one arm, which was followed by coldness of the member and paralysis, and a line of demarkation was soon established above the elbow. The late Dr. Alden March saw the case with him, and amputation was advised. When cut, the blood flowed like venous blood. The patient recovered, after extensive sloughing.

Dr. MCNAUGHTON remarked that this case illustrated the effect of paralysis upon the circulation, which seemed to be to coagulate the blood. This was the only case of the kind that he had observed in a practice of over fifty years.

This patient was entirely temperate, and of sedentary habits.

Dr. VAN DERVEER presented three specimens of spleens, two of them unusually large, and then gave

the following case: Mrs. B., æt. 36; married six years; had menstruated regularly, but not freely; ceased three months previous to death. Has never had intermittent fever. Had been under treatment at the Woman's Hospital, N.Y., in the fall of 1870, for no specific disease. She never was pregnant; her health had not been good for several years; she was laboring under an impression that she had cancer, and consulted Dr. March regarding a tumor in the breast. The tumor was first discovered in the left side in the summer of 1872. At the time of her death she was being treated by an eclectic in this city, for uterine disease.

Sectio cadaveris.—Nothing of importance found but an enormously enlarged spleen, which weighed nearly four pounds, measured in length 10½ inches, and was 5 inches in width at the broadest extremity and 4 inches at the narrowest. In thickness 3½ to 4 inches. Capsule firmly adherent. On section it covered the knife with fat. There was extensive peritonitis from the left inguinal to the left lumbar region, and the intestines were distended with fluid.

Dr. Bright (On Abdominal Tumors and Intumescence) says, "The spleen is an organ which, both from the obscurity in which its natural functions are involved, and from the situation which it occupies in the body, presents when diseased some difficulties in regard to diagnosis which are not shared by many other organs. Moreover, its healthy condition probably admits of so much variety, and so many changes as to bulk and consistence, that in a pathological point of view it is not always easy to make out the limit at which morbid change or degeneration of structure actually begins."

Dr. Bright speaks of spleens in Guy's Museum, one weighing only thirteen ounces and ten grains, and an apparently healthy one weighing nearly two pounds.

Rokitansky says of enlarged spleens, "A coagulable fibrinous deposit takes place, and the tumor, therefore, in proportion to the amount of coagulation becomes hard, elastic, and indurated; the parenchyma is of the reddish-brown color of fresh muscle, and presents on section a fleshy (sarcomatous) appearance; by degrees the coloring-matter is absorbed; the organ then presents a pale though yellowish or reddish-white appearance, and resembles fibrin that has been washed.

"During the hyperæmia the fibrous trabeculæ also increase in quantity and toughness, so that the tumor becomes more resistant; the fibro-serous capsule is also rendered more opaque, and is thickened; it is invested with a cellular pseudo-membrane, resulting from peritoneal inflammation, and is thus attached to the abdominal parietes."

He also speaks of "*fleshy hardness with enlargement,*" and remarks, "In this state the spleen often attains to a prodigious size, filling up the whole left side of the abdomen. It produces very little constitutional irritation, and chiefly injures by its bulk and its tendency to favor serous effusions. It is astonishing with what rapidity this enormous growth occasionally takes place; but in this respect we are liable to be deceived, for it is attended by so little pain that in many cases the increase has been taking place gradually long before some accidental circumstance leads to its discovery."

Microscopical Appearance of the Large Spleen.—The trabeculæ and Malpighian tufts are enlarged, as well as the blood-vessels; the whole tissue seems very much hypertrophied. No abnormal deposits, infiltration, or pathological conditions are evident excepting hypertrophy.

Dr. J. B. STONEHOUSE presented cases by which the hæmostatic properties of ergot were proved, and remarked, "About one year ago I became interested, from the statements in foreign and American journals, in the alleged hæmostatic properties of ergotin. Procuring some, I determined to test it as far as my practice permitted. The solution used was in the proportion of a half-drachm of ergotin to the drachm of water."

Dr. Stonehouse presented notes of five cases in which its use was successful, and hoped others would give it a trial, and thus lead to a more extensive use, which he believed it to deserve.

OBITUARY.

DR. HUGH L. HODGE, the son of Dr. Hugh and Maria Blanchard Hodge, was born in this city on the 27th of June, 1796. His father studied medicine with Dr. Cadwalader, served in the army, subsequently practised his profession in Philadelphia, where he was a Fellow of the College of Physicians, and died in 1798.

Having graduated with the highest honors at Princeton College, N.J., in 1814, young Hodge studied medicine at the University of Pennsylvania, as a private pupil of Professor Caspar Wistar. He took his degree in 1818, and, as was then a frequent custom, he went to India as surgeon to a merchant-vessel. Returning home, he began the practice of his profession in 1820, and married Miss Margaret Aspinwall, of New York. He became physician to the Southern Dispensary, afterwards to the Philadelphia Dispensary, in 1823 physician to the Almshouse Hospital, and in 1830 Obstetric Physician to the Pennsylvania Hospital. His exertions in the cholera hospitals in 1832 obtained the recognition of a vote of thanks and a silver pitcher from the city.

Dr. Hodge's career as a teacher began in 1821, when he took the private anatomical class of Dr. W. E. Horner, who was in Europe. In 1823 he became Lecturer on Surgery at the Medical Institute. But the Professorship of Obstetrics and Diseases of Women and Children in the University of Pennsylvania, conferred on him in 1835, was the main work of his life. He filled this important post until 1863, with a dignity and faithfulness which many practitioners all over our country will remember, and on his retirement was constituted Emeritus Professor. In 1871 he received the degree of LL.D. from Nassau Hall, Princeton.

A very large family- and consultation-practice flowed in upon Dr. Hodge, strangers coming to the city, especially from the South and West, to obtain the advantages of his advice and treatment. Few physicians have ever possessed the confidence and love of their patients in a larger degree. His great and varied experience he utilized in the invention and improvement of obstetric instruments; the best-known being his forceps, his pessaries of several forms, and a cephalotribe.

Dr. Hodge's principal literary work was his "System of Obstetrics," a large quarto, containing an admirable exposition of the views which he had so ably presented to his classes for twenty-eight years. This book, which appeared in 1863, had been preceded by a smaller one, on the "Diseases Peculiar to Women," in 1860. During the first few years of his professional life he was one of the editors of the *North American Medical and Surgical Journal*, and contributed to it a number of reviews and original articles. Papers by him appeared also in the *American Medical Journal*, and in the *American Journal of the Medical Sciences;* two of the latter, on "Synclitism of the Fœtal Head," excited a good deal of discussion a few years ago. A number of his introductory lectures were also published from time to time: one, on "Criminal Abortion," after being several times reprinted, was lately issued afresh under the title "Fœticide." He would have been a much more prolific writer, but for the pressure of his professional engagements during so many years.

Dr. Hodge was not only a man of singular modesty, purity, and temperance, but of earnest and devoted piety. He was at the same time positive in his opinions and courteous in defending them. His conscientiousness in the performance of duty in every relation of life was one of the most marked features of his character. To the last he was at work: on the very day that his brief final illness began, he saw patients, and was occupied with his amanuensis in the preparation of an article on "Cephalotripsy."

He died of angina pectoris, after only twenty-six hours of suffering, on the 26th day of February, leaving behind him a character of spotless integrity. Five sons survive him, only one of whom, Dr. H. Lenox Hodge, has adopted the same calling.

GLEANINGS FROM OUR EXCHANGES.

The Effects of Quinine upon the Uterus (Von Josch: *Wiener Med. Presse*, No. 36, 1872).—The important consideration appears to be whether we dare assume that quinine acts upon the fibres of the sympathetic; but we have to consider this question as unsatisfactorily answered at present. The author, who appears to have had considerable experience both in clinics and private practice, says that most physicians must have noticed that in the early stages of gravidity quinine possesses the power of producing slight contractions in the uterus. It possesses the same power in the post-partum period. Its use, however, is at least "superfluous" in the latter stage, if considered as a means of producing efficient contractions of the womb. In order to admit this, we have but to consider the causes which produce retention of the placenta. The most frequent are:

1. Atony of the uterus.

2. Irregularity of the uterine contractions, contractions operating in the wrong direction (Nägele, Grenser), tonic spasms (*strictura uteri spastica*), and clonic spasms (Hegar); or

3. Abnormally firm adhesions.

The rarer causes are—(*a.*) Abnormal position of the placenta,—very deep or in the uterine end of the Fallopian tube.

(*b.*) Narrowness of the parts concerned in parturition, especially in the early months of pregnancy, or secondary narrowness in consequence of impaction of the rectum or fulness of the bladder.

(*c.*) Abnormally large placenta (?), *Placenta succenturiata*, and deformities of the placenta.

(*d.*) Considerable deflexion of the uterine axis from the central line of the pelvic canal.

Simple presence of the loose placenta in the vagina cannot be considered retention of the *after-birth*, because in such a case simple traction upon the umbilical cord will bring away the placenta.

If the physician desires to use a drug to produce contraction of the uterus, he could desire such a remedy only in cases of atony of the uterus; for in the second condition already noted any means productive of contractions could in no way relieve the already faulty direction of the contraction. And in the third instance no remedy is of avail. These cases of firmly adherent placenta are so rare as to be denominated "myths" ("*Gespenste*," Credé). In cases of atony of the uterus where post-partum hemorrhage is threatened, the author thinks that "Credé's method" is far superior to any drug.

He says that since this method has been generally taught and practised in *normal labor*, atonic conditions of the uterus are much less frequent than heretofore. Since the method is simple, every obstetrician should try it before resorting to one more complicated. The conclusions concerning the foregoing questions are:

1. Empirically it is very probable that contractions of the uterus may be produced in the *post-partum* period by the administration of a large dose of quinia, although we do not know the physiological connection.

2. Its use, like that of the much-vaunted ergot, in the post-partum period, is superfluous, and is to be rejected for more exact and fitting treatment.

Treatment of Aneurisms.—Prof. Billroth, in the sixth edition of his work on the General Principles of Surgery, 1872, describes the following methods: 1. Compression of the tumor itself. 2. Compression of the trunk above the tumor; and of the different modes of applying the pressure he enumerates that with the finger, that by forcible flexion, and that by various compressors, tourniquets, etc. 3. Ligature of the artery by Anel's, Hunter's, and Wardrop's methods. 4. Injections of various kinds, as of perchloride of iron and of solution of ergotin. 5. Electro-puncture. 6. Ablation of the entire swelling (method of Antyllus). In commenting upon these different methods, Prof. Billroth remarks that sometimes one and sometimes another is to be preferred. As a general rule, however, in view of the very numerous and favorable cases that have been reported from the employment of compression, he thinks this should be first tried, and not too early given up. When, as is usual in traumatic cases, the tumor is widely diffused, Antyllus's method, the complete ablation of the whole mass, is to be preferred. It is quite practicable with good assistants. If this plan be not adopted, then recourse must be had to Anel's or Hunter's method. Ligation of the larger vascular trunks would always be performed as the best and simplest means for the cure of aneurism, were it not that secondary hemorrhage takes place so frequently from the part ligatured. Professor Billroth suggests that some plan may even yet be discovered which possesses the advantages without the disadvantages of the ligature. Injection with liq. ferri is least available in cases of spontaneous and traumatic aneurism. In varicose aneurism and aneurismal varix, the ligation of the artery above and below the opening is the most certain means of cure.

Treatment of Psoriasis (*La France Médicale*, January 15, 1873).—Psoriasis is not in itself a serious disease, says M. A. de Montméja, but it is obstinate, and those who have once been affected by it are very liable to relapses. It is often hereditary, manifesting itself only when the adult period is reached, after which it may be either intermittent or inveterate. In the present state of our therapeutical knowledge, we must not imagine that we can effect a radical cure of psoriasis; we may clear the skin, or hasten the evolution of an attack, but it is impossible to prevent relapses. The treatment is divisible into that by local and general means. The general treatment consists in the administration of mild and frequently repeated aperients, and of arsenical and sulphuretted preparations, as well as of those containing cantharides. M. Hardy prefers small doses of the arseniate of soda to the other preparations of arsenic. M. de Montméja has obtained considerable success from the employment of two drops of tincture of cantharides in a glass of eau sucrée, the dose being increased up to thirty drops per diem. Its use, however, requires extreme care and vigilance. Copaiva is sometimes very useful when given internally. In addition to these means, the waters containing sulphur, of Saint Honoré-les-Bains, Baréges, Aix-en-Savoie, may be tried, especially in inveterate cases. The local treatment that is found most beneficial is the application of vapor baths, and either warm alkaline or sulphurous baths, with ointments containing the empy-

reumatic oils. It is rare for sulphuretted oils to prove of any service, and if mercurial ointments are used, care should be taken when the scabs have fallen off, lest salivation be induced. The oil of Cade, with three parts of lard, is very useful.

"NORMAL" OVARIOTOMY.—The *Medical and Surgical Reporter* learns from a correspondent in Georgia that Dr. Battey's extirpation of the normal ovaries "is a failure. The menstrual molimen and sanguineous discharge, with great suffering, still occur monthly."

MISCELLANY.

ERRONEOUS.—The *Pacific Medical and Surgical Journal* finds fault with one of our cotemporaries for stating that "three hundred women have made application to study medicine in San Francisco," and justly thinks that "a statement so improbable on its face" ought not to be circulated, at least without the authority for it being given.

ACCORDING to the *Lancet* of February 22, there are at present more candidates for positions in the British naval medical service than there are vacancies to be filled,—a circumstance which has not occurred before for twenty years. A large proportion of the applicants are Irishmen; sixteen being of this race to one Londoner and two Scotchmen.

VISITORS FROM BALTIMORE.—The building committee of the John Hopkins Hospital of Baltimore were in Philadelphia March 22, for the purpose of examining the Episcopal Hospital. The visitors while at that institution made themselves thoroughly acquainted with its construction and management.

FAILED.—It will be a matter of sincere regret to the many friends of the Jefferson Medical College if, as we are told, their application to the State Legislature for an appropriation towards the establishment of a hospital in connection with the school was denied. The grounds of the refusal are not known to us.

COMMENCEMENT.—The Philadelphia College of Pharmacy held its Fifty-second Annual Commencement on the 18th inst. The graduating class numbered ninety-four. The valedictory address was delivered by Prof. Robert Bridges, M.D.

DEATHS.—Dr. Uriah G. Bigelow, a prominent and much-respected practitioner of Albany, N.Y., died on the 24th of February, in the 53d year of his age.

Dr. Abner Phelps died in Boston on the same day, at the age of 95.

ON the 24th of March the following gentlemen were elected resident physicians to the Philadelphia Almshouse Hospital: Drs. Edward T. Bruen, James M. McCauley, John M. Keating, C. K. J. Miller, Juan G. y Guiteras.

DR. BENCE JONES, of London, the well-known authority on medical chemistry, is reported to be very ill with ascites and anasarca.

A CORRESPONDENT of the *British Medical Journal* has been "requested to attend gratuitously a woman who claimed exemption from surgical fees 'because she had a cousin whose friend was a medical man.'"

DISINFECTANTS.—A student, undergoing his examination, was asked what was the mode of action of disinfectants. He replied, "They smell so badly that the people open the windows, and the fresh air gets in."

MEDICAL DIRECTOR Joseph Beale, U.S.N., has been appointed Inspector-General of Hospitals and Fleets, his duties to begin on April 1.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending March 22, 1873, were 334; 193 adults, and 141 minors. 13 were of bodies brought from the country; making the mortality of the city 321. Among the assigned causes of death were:

Consumption of the Lungs	49
Other Diseases of the Respiratory Organs	65
Diseases of the Circulatory Apparatus	20
Diseases of the Brain and Nervous System	47
Diseases of the Digestive Apparatus	25
Zymotic Diseases (13 from Scarlet Fever)	31
Typhoid Fever	15
Casualties	5
Cancer	6
Diseases of the Urinary Organs	3
Suicide	1
Murder	1
Debility (including "Inanition" and "Marasmus")	24
Still-born	16
Old Age	11

(The interments reported for the week ending March 23, 1872, were 416.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER.		BAROMETER.
	Max.	Min.	(2 P.M.)
Mar. 16	52.0°	37.0°	30.10 in.
" 17	45.0	33.0	30.39 in.
" 18	61.0	33.0	29.99 in.
" 19	56.5	42.5	30.04 in.
" 20	42.5	40.0	29.72 in.
" 21	41.0	31.0	29.76 in.
" 22	46.0	35.0	29.97 in.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 18, 1873, TO MARCH 24, 1873, INCLUSIVE.

MCKEE, J. C., SURGEON.—Granted leave of absence for six months, on surgeon's certificate of disability, with permission to go beyond sea. S. O. 57, A. G. O., March 19, 1873.

BILL, J. H., SURGEON.—Assigned to temporary duty at David's Island, New York Harbor. S. O. 55, Department of the East, March 22, 1873.

ALDEN, C. H., SURGEON.—Granted leave of absence for four months, with permission to go beyond sea. S. O. 56, A. G. O., March 18, 1873.

TILTON, H. R., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Wadsworth, New York Harbor. S. O. 55, c. s., Department of the East.

SATURDAY, APRIL 5, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

(Continued from page 404.)

LECTURE VI.

MORBID GROWTHS IN THE LARYNX AND TRACHEA.

THE frequent use of the laryngoscope, of late years, has developed the fact that morbid growths of the larynx are of much more frequent occurrence than was formerly thought to be the case.

The lecturer gave a short historical sketch of the subject, from the earliest reported case of Koderick of Brussels, who in 1750 removed a laryngeal polypus through the mouth, down to the present time; in which he gave full credit to the most important monographs upon morbid growths in the larynx: those of Ehrmann, of Strasburg; Horace Green, Buck, and Elsberg, of New York; Morell Mackenzie, of London; and he referred, in addition, to the labors of Türck, Gibb, Cutter, Voltolini, Schrötter, and others.

The symptoms of a growth in the larynx are much the same, whatever may be the nature of the neoplasm, varying of course with its size and location, the character of its attachment, and its consequent interference with vocalization, respiration, and deglutition. These symptoms are cough, dysphonia, dyspnœa, dysphagia, and pain. Some growths do not give rise to any characteristic symptoms, and are discovered on laryngoscopic examination only.

Cough is present when the tumor encroaches on the glottis, or is of large size. It is dry, or accompanied with expectoration of mucus, or mucus and blood, according to the nature of the growth, and the inflammatory condition of the larynx. The sound of the cough is clear, hoarse, muffled, brazen, or aphonic, as the case may be.

Dysphonia occurs to a greater or less extent according to the interference with the due vibrations of the vocal cords exerted by the growth; and thus a tumor of considerable size, if at a distance from the glottis, may not give rise to marked dysphonia at all. When the growth is so situated as to encroach on the glottis or the vocal cords at intervals only, the hoarseness or aphonia, as the case may be, will be intermittent; so that the voice shall go and come, as it were, several times during the utterance of a single sentence. Usually there is a characteristic staccato mode of utterance, suggestive at once, to the practised ear, of a tumor in the larynx.

Dyspnœa exists only when the growth is large, or when there is intercurrent tumefaction from catarrhal inflammation. Dyspnœa from a pendent tumor can sometimes be relieved by change of posture. Suffocation is sometimes produced by the impaction of a morbid growth obstructing the glottis, some cases of which were narrated from the lecturer's personal experience.

Dysphagia is not produced unless the growth occupies the epiglottis, the posterior portion of the larynx, or encroaches on the pharynx.

Pain is unusual, though there is often an aching sensation, or a feeling of the presence of some foreign substance.

If the growth has acquired comparatively enormous proportions, some evidence may be present externally in an altered configuration of the larynx.

Occasionally portions of a growth become detached by cough, and are expectorated. Once in a while a growth is spontaneously detached; and at other times absorbed.

The most frequent exciting cause of growths seems to be catarrhal inflammation. Quite a large proportion of growths occur in connection with cases of tuberculosis and syphilis; though the tumors produced in such instances have very rarely any characteristic feature belonging to the tuberculous or syphilitic dyscrasia.

The most frequent variety of growth is the papilloma; but fibroma, myxoma, angeioma, sarcoma, epithelioma, and many other varieties have been observed. The papillomatous tumors are frequently multiple; the others usually single. The papillomatous growths are not apt to recur except in a phthisical patient.

These growths have been encountered at all ages. Sometimes they are congenital; though they are most frequently met with in individuals from twenty to fifty years of age. They occur more frequently in males than in females. Morbid growths may occupy any portion of the larynx, but their most frequent seat is upon the vocal cords.

A morbid growth of the larynx is a very serious affection, even if clinically benign in structure; and if of such a size as to interfere with the functions of respiration and vocalization, it demands removal by surgical procedure. Syphilitic formations, even when of comparatively large size, are occasionally amenable to constitutional anti-syphilitic treatment.

A growth of the larynx may be removed by an operation carried on through the mouth; through the incision of lateral pharyngotomy; or through the incision of laryngotomy, partial or complete, anterior or lateral.

Removal through the mouth is effected under laryngoscopic manipulation; though there are at least two cases on record of removal through the mouth in ante-laryngoscopic days: those of Koderick, in 1750, and Green, in 1845. The procedures carried on under laryngoscopic manipulation are: cauterization, scarification followed by cauterization, crushing with forceps, evulsion with forceps

or écraseur, excision with knife, scissors, wire loop, or galvano-cautery.

Small soft growths are sometimes amenable to destruction by caustics. For this purpose we employ nitrate of silver, chloride of zinc, acid nitrate of mercury, nitric acid, chromic acid, London and Vienna paste. The caustic material is conveyed in some safe special appliance, and kept in contact with the parts for a few seconds, in order to secure the formation of a slough; the operation being repeated at intervals of a few days. The first operation usually produces a distressing spasm, especially if any of the caustic material reaches the healthy mucous membrane, the tumor itself being much less sensitive. It is, therefore, essential that the operator should be certain, by repeated practice with blunt instruments, that he can touch the desired spot. The surface of the cauterizing instrument, whether brush, sponge, roughened metal, glass bulb, or solid stick, should not be large enough to cover the entire surface of the growth at once, inasmuch as the caustic spreads rapidly. The part may be touched two or three times at different points at each operation.

[Various instruments were exhibited and explained, during this lecture, for the safe conveyance of caustics within the larynx; and also various forms of forceps, knives, snares, galvano-cauteries, etc., were demonstrated; but the reporter refers the reader for details to the various works on laryngeal surgery, and to the illustrated catalogues of the surgical instrument makers.]

Forceps are, however, much more useful in the removal of laryngeal growths, in the vast majority of cases, than any other instruments. They must be properly curved, slender, and strong; and their jaws must present in the direction of the tumor which is to be seized. One pair of forceps, therefore, will not suffice for every case. Tumors are not by any means always removable at one operation, unless they are small, or of very firm consistence. Usually small portions of the growth are broken off in the jaws of the forceps, thus necessitating the frequent repetition of the operation. When as much of the growth has been removed as possible, its remnants, if any remain, or the base from which it was developed, should be freely cauterized, to repress repullulation.

The knife, and the scissors—or rather the bladed-forceps—are sometimes used to excise a growth. A large growth can sometimes be partially severed from its base in this way, and thus rendered prominent so as to become more readily seized with the forceps. Or the ventricular band may be incised so as to afford access to a growth in the ventricle. Sometimes a minute growth may be pierced at its base by a lance-pointed knife, and be detached by pushing the instrument through its root of attachment; under which circumstances it falls and is coughed out.

The wire snare is sometimes used to lasso and detach pedunculated growths; but, though much extolled by some manipulators, is not much thought of by the lecturer, who has rarely been able to use it with any satisfaction.

The galvano-cautery, in the form of blade, blunt probe, or loop, is used with a great deal of success for the destruction or removal of laryngeal growths. Some surgeons, as Voltolini of Breslau, use no other instruments, even in the entire treatment of the whole class of laryngeal diseases requiring topical interference. The only danger to be apprehended is the production of œdema, or of violent inflammation; but the numerous evidences in favor of this treatment lead the lecturer to believe that this danger is quite exceptional.

Electrolytic treatment is hardly applicable to the treatment of laryngeal growths, on account of the impracticability of retaining the needle electrode in the tumor for a sufficient time to set up efficient electrolytic action.

Almost all laryngeal growths can be satisfactorily treated through the mouth, by some of the methods mentioned. When the growth is very large, or is situated beneath the glottis, or from other reasons dyspnœa is great, or asphyxia threatened, it is advisable in special cases to perform tracheotomy before undertaking extirpation, in order to secure safety as to respiration; but a resort to this operation is rarely necessary.

Several operations are performed for gaining access to a laryngeal growth from the exterior of the body. They are undertaken in cases where it is impossible to remove the neoplasm through the mouth; where the necessities of the case do not admit of delay; where the growth is of great size, and of great extent and implantation; where it is very vascular; and where it is clinically malignant.

The usual operation consists in external division of the larynx in the middle line. The thyroid cartilage is exposed, and divided by knife, scissors, or saw, as the case may demand; but the cricoid cartilage is usually respected. Some surgeons divide the cartilage by successive short strokes of the knife from the exterior; others, and the lecturer among them, penetrate the crico-thyroid membrane, and divide the cartilage from below upwards. If the saw is used, of course it must not be carried into the interior of the larynx. In dividing the cartilage, care is to be taken to keep the knife in the middle line, so that it shall pass between the vocal cords without injuring them. The separated wings of the thyroid cartilage are then kept asunder by suitable blunt hooks, and the morbid growth is removed by forceps, snare, knife, scissors, or galvano-cautery, as the case may be; after which the stumps are thoroughly cauterized. There is usually a great deal of spasmodic heaving of the larynx during the removal of the growth, spattering blood over the person of the operator and his assistants. The blood should be prevented from flowing down into the lungs by being mopped up with small bits of sponge securely fastened to a holder.

After the operation the parts are united with adhesive strips externally and covered with a simple dressing. The room in which the operation is performed should be warm, and the atmosphere of the apartment kept saturated with steam for a few days.

Some operators perform tracheotomy before divid-

ing the larynx, but, as has been shown by Dr. Ephraim Cutter, of Woburn, Mass., this precaution is rarely necessary.

The lecturer expressed himself as opposed to the use of anæsthetics in the performance of these operations, inasmuch as the integrity of the glottis was already greatly compromised, and a diminution in the amount of oxygen respired might lead to fatal results despite the prompt opening of the air-passages, as he had witnessed on more than one occasion; and he recalled several instances where artificial respiration had been requisite to save the patient's life.

The operation of sub-hyoid pharyngotomy, as suggested by Bichat, Vidal, and Malgaigne, and performed with sundry modifications by Prat, Follin, Langenbeck, and Debrou, was described; but, inasmuch as the lecturer expressed his concurrence in the opinion of Mackenzie, that in the majority of the cases suitable for this operation the tumor could be removed through the mouth, we do not consider it necessary to enter into details.

Mention was also made of Luschka's proposed operation for gaining access to growths in the ventricles by lateral division of the thyroid cartilage.

Tumors of the trachea are much less frequent than tumors of the larynx. Cases have been recorded by Morgagni, Ruysch, Baillie, Gibb, Türck, Schrötter, and others. Some cases of involution of the tracheal parietes from the pressure of growths from the outside have been incorrectly reported as tumors of the trachea. They would give rise to phenomena of obstruction similar to tracheal tumors, but should be differentiated from them. Tracheal tumors are usually small; large size being incompatible with respiration; so that, as a rule, they would not give rise to any specially characteristic symptoms during life.

Laryngoscopic examination has given occasion to the recognition of tracheal tumors, but most of the cases reported were post-mortem. Schrötter has succeeded in removing a tracheal tumor under laryngoscopic manipulation; but this requires much more skill than falls to the lot of the mass of the profession; so that the removal of such growths would generally require the external division of the trachea.

Tumors of the bronchi have also been observed by Türck and others; but on post-mortem examination only. It would be exceedingly difficult to diagnose the presence of an intra-bronchial growth, since the symptoms of obstructed respiration to which it would give rise might as well be explained by other more likely conditions. It would be the merest accident that a tumor high up in a primary bronchus could be detected in the laryngoscopic image; and it would be entirely out of the reach of direct surgical interference.

CANCER OF THE LARYNX AND TRACHEA.

Both primary and secondary cancer have been observed in the larynx and in the trachea. It is doubtful if there are any special symptoms by which primary cancer could be distinguished at an early date; but in its maturer stages it is readily recognized in the laryngoscopic image by a peculiar irregular, nodulated, vascular, and sometimes ragged appearance; and by the lymphatic involvements, the cachectic expression, and sometimes the lancinating pains. Portions of the formation can readily be removed for microscopic examination. Cancer of the larynx may be scirrhous, medullary, or epithelial. It may affect any portion, but seizes most frequently upon the epiglottis first, and gradually extends. The tongue becomes involved by extension of the disease, and sometimes the cancer of the larynx is preceded by extension from the tongue, or extension from the œsophagus.

The symptoms are at first those of catarrh, and subsequently those of laryngeal obstruction generally, dyspnœa, dysphagia, dysphonia, and so on.

The disease is necessarily fatal. Proposals have been made to exsect the larynx; but, even if this could be safely done, it is likely that the disease would soon be manifested in the neighborhood.

Cancer of the trachea is a very rare affection. It could hardly be diagnosed during life, but would afford symptoms of obstruction or stenosis. Such symptoms, in connection with cachexia, might lead one to suspect cancer of the trachea, but only the microscopic examination of expectorated fragments could establish the diagnosis with certainty. But few cases of cancer of the trachea are on record.

ORIGINAL COMMUNICATIONS.

TWO CASES OF ANILINE-POISONING.

BY ALFRED L. CARROLL, M.D.,
University of New York.

THE case of aniline-poisoning reported in the *Medical Times* of March 1, by Dr. Richardson, recalls two similar instances occurring in my practice last summer.

On the 15th of August, 1872, I was asked to see M. B., an unmarried woman, aged 30, who had a localized eczematous eruption affecting both knees and extending some inches above and below the joints. There was considerable tumefaction, much redness, and intolerable itching of the skin; the condition being that of *eczema rubrum*. The circumscribed and symmetrical character of the affection, coupled with the absence of constitutional disturbance of any sort, puzzled me at first; but, while questioning my patient, I spied, under the bed, a strip of red flannel, the brilliant scarlet hue of which told clearly of aniline dye. Following up this clue, I learned that she had had "rheumatic" pains in her knees, and, believing that there was some special virtue in red flannel, had purchased a couple of yards of that popular remedy at a village shop, and bandaged her knees therewith for a fortnight previous to my visit. The peculiar color of the flannel, and the limitation of the eruption to the regions covered by the bandage, placed

the diagnosis beyond doubt. To allay the irritation, I first prescribed the ordinary acetate of lead and opium lotion,

℞ Liq. plumbi subacetat., f℥ij,
Tinct. opii, f℥j,
Aquæ, Oj;

and afterwards benzoated oxide of zinc ointment, under which, with an occasional saline laxative, recovery speedily ensued.

Only a few days afterwards, I was consulted by a gentleman who had on his left wrist a band of vesicular eruption, forming a complete bracelet, which he himself attributed to some accidental contact with "poison-vine" (*Rhus radicans*). The exanthem being confined to a covered situation, however, led me to further investigation, and I discovered that he had shortly before bought a pair of thread gloves, the wrist-bands of which were ornamented by a broad stripe of aniline purple. Owing to the warmth of the weather, he informed me, he had never put on the right glove, the left alone having been worn for several days. In this case, as in the preceding one, the disease yielded readily to local treatment.

I believe that with aniline compounds, as with lead, an exceptional susceptibility exists in certain persons, which is not shared by the majority. Just as we occasionally meet with instances of saturnine poisoning from drinking water conveyed through lead pipes which harmlessly supply thousands of households, so numbers of people habitually wear articles dyed with aniline, without suffering evil effects. Notwithstanding that the market is flooded with such wares, which find very many purchasers, I have met with but one case of poisoning besides those reported above,—that of a gentleman whom I saw in consultation four or five years ago, whose feet and ankles were covered with vesicles from some brilliantly-colored striped socks which he had been wearing for several weeks in ignorance of their toxic property.

New Brighton, Staten Island, N.Y., March 21, 1873.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

SURGICAL CLINIC OF PROFESSOR S. D. GROSS, M.D.

Reported by Frank Woodbury, M.D.

LITHOTOMY.

THIS middle-aged man comes from Williamsport, Pa., with a history of having suffered, for at least three years, from a vesical calculus, his symptoms being so well marked as scarcely to admit of a doubt regarding the correctness of this diagnosis. He complains of the usual irritability of bladder, and almost constant desire to urinate, which act has lately been accompanied by gradually increasing pain and difficulty, the stream frequently being stopped while in full flow; and even when this does not occur there is a feeling of incomplete emptying of the bladder after micturition. His general health becoming impaired, he has finally been led to seek our aid, hoping that a surgical operation will relieve him of all his troubles by removing their source.

The patient being under the influence of chloroform, we proceed to examine him; and here I pause to again impress upon you the importance, whenever you perform this operation, of making it an invariable rule to always sound your patient's bladder and positively find the stone before you proceed to operate, no matter how strong the physical signs may be, or whether or not you may have found it on previous examinations: by this means you will avoid a serious and perhaps fatal mistake,—one that I regret to say has been committed quite a number of times. When you examine your patient, let him be perfectly nude and lying on his back in bed, with a blanket thrown over him to ward off a possible chill; never hamper yourself by attempting to conduct the examination with the clothing only partly removed. A sound with an abrupt curve is the best to use in exploring the bladder, especially where you have to deal with long-standing disease of the organ, and probable enlargement of the prostate gland. As this is moved in the bladder, you hear the characteristic sound produced by striking the metallic instrument against the stone, the resistance from which is distinctly evident to my hand. The grating or friction sound, by itself, is frequently delusive, as it may be produced by a fasciculated condition of the bladder, or an incrusted condition of its mucous membrane,—particularly at the bas-fond of the organ,—caused by a lamellated deposit of earthy material from the urine; this alone, therefore, is insufficient evidence of a calculus, and you should never be led to cut a patient on such an incomplete diagnosis. A sounding-board has been devised, which, when attached to the handle of the sound, intensifies the metallic click produced on striking the stone; but I have never had occasion to use it, feeling confident that if a man cannot find the calculus without its aid, he certainly will not be able to do so with it. The bladder should be full of urine at the time of examination, and the rectum empty. If the concretion is small, it might readily be lost in a large amount of fluid, and the surgeon be unable to find it; in such a case the hollow sound is of great advantage; by its aid the urine can be gradually drawn off so as to facilitate the discovery of the stone, or, on the other hand, tepid water may be cautiously injected through it, so as to give the requisite degree of distention to the bladder, when it contains too little fluid. If the stone is not readily found, rotate the instrument so as to examine the fossa immediately behind the prostate gland. When this gland is enlarged by disease, or hypertrophied by old age, a calculus might readily be concealed in this situation, from which, however, it may easily be dislodged by inserting the forefinger into the rectum and lifting up the base of the bladder.

When the stone is found, the question comes up as to the relative merits of lithontripsy and lithotomy, and their applicability to the individual case. Shall the stone be crushed, or cut for? Although the relative mortality of the two modes of operating is in favor of crushing, yet the liability to relapse is much greater than when the calculus is removed bodily. Where the patient is in a condition to bear the operation, and the concretion is ascertained to be large, lithotomy, in my opinion, should always be preferred. Whereas in lithontripsy, or lithotrity as it is oftener called, some of the fragments almost inevitably remain to act as nuclei for fresh growths, this is entirely avoided in lithotomy, for if any fragments exist they will either be removed at the time of the operation, or be washed out in the course of the treatment. As to the mortality after this operation, it depends very largely upon the general condition of the patient, and the state of his bladder and ureters at the time of operating. With proper treatment of the patient before and after the operation, the danger is very much decreased. Although in adults the general rate of deaths is about one to eight or nine recoveries, children rarely die from the opera-

tion. I have performed the lateral operation upon fifty-two under the age of puberty, with but a single fatal result. I attribute my success in these cases, as well as in adults, not only to the care exercised in performing the operation, and strict after-treatment, but also to my rule of never operating until the patient has gone through a course of preparatory treatment. If the patient is brought from a distance, you should not even sound him, until he has recovered from the fatigue of his journey and become somewhat accustomed to his new surroundings.

The prognosis of this affection varies. Some cases are recorded where the stone has broken in the bladder spontaneously, causing the death of the patient from cystitis; in other cases the pressure of the stone has led to ulceration and perforation of the wall of the bladder, producing extravasation of urine, followed generally by fatal peritonitis in a few days, or leading to extensive inflammation and suppuration, seriously threatening life. In every case, the stone being a constant source of irritation to the mucous membrane of the bladder, there is always more or less cystitis, followed by disease of the ureters and kidneys, from extension of the morbid action, thus interfering with the important function of excretion.

The first symptoms produced by a vesical calculus are those of functional disorder; but these are soon followed by others denoting structural change. The mucous membrane of the bladder, from increased vascularity, produced by the constant irritation, soon passes into chronic inflammation, and becomes covered with granulations. The muscular coat becomes hypertrophied from constant ineffectual attempts to contract upon and expel its contents, and the fibres may separate in one or two places, forming hernia of the bladder, or a sacculated bladder. The obstruction to the flow of urine is augmented by the prostate gland, which early becomes diseased and greatly enlarged, in some instances encroaching seriously on the rectum, interfering with its functions and producing hemorrhoids. Although the symptoms may be palliated and the patient's life protracted by hygienic and medical means, the only effective treatment is the removal of the concretion by an operation.

Having determined upon performing lithotomy by the lateral operation, and the patient being ready, we bring him to the foot of the bed, with his sacrum resting upon its edge. His knees and thighs are strongly flexed and held widely apart by assistants, the perineum is shaved, and the staff-holder introduces the instrument into the bladder and hooks it up under the pubic arch, so as to pull it away from the rectum. The bowel was emptied by enema this morning, and I introduce my finger into it to make it contract, so as to be out of the way. During the operation, protrusion of the intestine, through the opening, is not uncommon, especially in the straining efforts of children; and in these cases great care is required to avoid wounding the rectum.

The operation, performed in the usual manner, enables me to introduce the lithotomy-forceps and extract this large calculus, which is of the uric acid variety. In a large proportion of the cases the stone is found to be of this kind. The phosphatic variety is generally considered to be due to some defect of innervation, or lesion of the spinal cord.

Hemorrhage following the operation is rare in children, but in adults, who have labored for a long time under vesical irritation, bleeding from the bladder and prostate gland is common. Sometimes the transverse perineal artery requires a ligature; but in most cases plugging with pieces of ice, or cotton impregnated with Monsel's solution, will be found sufficient. If there is no hemorrhage in this case, the wound will be left in its present condition, after washing out the bladder with warm water by means of a large syringe. I do not insert a canula, as it is of questionable utility and serves as a source of irritation. The patient is placed in bed upon the usual oil-cloth and draw-sheet, and a full anodyne is given immediately, to relieve pain and irritation. The urine will pass through this aperture for the next thirty-six to forty-eight hours; then the tumefaction of the lips of the wound will close the orifice, and the fluid will pass by the natural channel. In a few days it will again flow through the wound, which, however, in fifteen to eighteen days will be completely closed by granulation.

The patient's bowels shall be confined for three or four days with opium, at the end of which time a mild purgative may be given. He must be kept clean, so as to avoid excoriations and bed-sores, and he will be given light but nourishing diet.

Ten days after the operation.—The patient has had no unfavorable symptoms, and is so nearly well that he will probably go home at the end of the week.

RHEUMATISM OF THE URINARY BLADDER.

This man, 39 years of age, complains of pain in the groins and frequent micturition, which attacked him two weeks ago and is increasing. He passes his water, on an average, about twenty times in the twenty-four hours, and is compelled to get up at night, sometimes twelve or fifteen times, for that purpose. The urine is never bloody, and he voids it in a very small stream with considerable straining, but without any particular pain at the time. He is troubled with some flatulence, constipation, and hemorrhoids, but his general health is not much affected, and he says he would sleep well enough at night if it were not for his bladder. He informs us that he has had rheumatism, but not since this trouble commenced.

On passing the sound, we detect no stricture or calculus in the bladder to account for the symptoms; which in all probability are produced by rheumatism or neuralgia, as the bladder is subject to these affections just as any other organ of the body is. We will, therefore, give him ten grains of quinine morning and evening for five days, and

℞ Morphiæ sulph., gr. $\frac{1}{8}$,
Vini colchici, gtt. xlv. M.

at bedtime, each night.

The morphia will relieve the irritability of the bladder, and the quinia and colchicum will act upon the rheumatism. If this is insufficient to procure for him good rest at night, without which his health cannot be restored or maintained, we might give opium or morphia suppositories at bedtime, or inject half a drachm of laudanum, or give morphia hypodermically, in addition. He shall be kept warm, in the house, and may eat light food; but coffee, pastry, and the red meats are interdicted.

One week later.—The patient reports himself as being much improved. He is now compelled to empty his bladder only seven or eight times in the twenty-four hours, and not oftener than four times in the night, instead of every half-hour, as before. He has no pain in his side, and no scalding or tenesmus.

There is marked improvement here; and in a short time he will have fully recovered. A full dose of morphia or quinia will frequently accomplish more than a dozen smaller ones, on the principle that when a man is hungry he wants a full meal. We must give medicine to accomplish a certain object, and should always give enough to obtain its full therapeutic effect. We will now give him

℞ Quiniæ sulph., gr. x,
Morphiæ sulph., gr. $\frac{1}{3}$. M.

which he shall take at night as before; and to modify the urinary secretion, he may take

℞ Infus. uvæ ursi, f℥ij,
Sodæ bicarb., gr. x.
M.—S. t. d.

(He returned three days later, and reported himself comfortable and almost entirely cured.)

CONGENITAL CYSTIC TUMOR.

The mother of this infant states that when it was born, six months ago, this tumor on the neck existed; although it has now attained a much larger size than then, and is still increasing.

On examining this swelling, we notice that it is of large size, and occupies the greater part of the left side of the neck, extending from the middle line in front, around on the side, and from the hyoid bone to the clavicle. Although it seems superficial, it probably sends ramifications deep among the muscles of the neck. It is compressible, although some parts are harder than others. The skin over it is natural, with no abnormal heat or discoloration, and no evidences of pain are elicited by pressure.

This belongs to the class of cystic tumors, which are frequently congenital, occasionally attaining a large size before birth, and continue to grow afterwards. Although they are sometimes met with in the axilla, breast, and other portions of the body, the neck seems to be the favorite seat in these cases. If we should open this it would probably be found to consist of a number of delicate, non-communicating cysts, varying from the size of a pea to that of a pullet's egg, containing a clear fluid resembling serum, and supplied with blood-vessels, nerves, and absorbents. The tumor may be unilocular, however, in which case its walls may have become quite thick from condensation of the cellular tissue.

As this is steadily increasing, its volume may become so great as to seriously affect respiration and deglutition. Several modes of operation have been suggested for the treatment of these cystic tumors in this situation. First, to open the sac and let it granulate; second, to insert a seton and leave it in long enough to excite adhesive inflammation; third, to draw off the fluid with a trocar and canula, and inject dilute tincture of iodine for the same purpose; and lastly, to make an incision over the tumor through the skin and dissect it out bodily. The last is the most effective of all, but it is not always feasible. We will puncture this and let out the fluid, hoping that sufficient inflammation may be excited by the knife to effect a cure, at least of the larger cysts.

TRACHEOTOMY PERFORMED BY GALVANO-CAUSTIC APPARATUS (*The Practitioner* for March, 1873; from *La France Médicale*).—This proceeding was originally introduced into practice by M. Amussat *fils*, in 1870, and was first performed on a boy aged thirteen. Dr. Amussat passed a curved needle carrying a double thread of platinum through the integuments, so as to embrace at the same time about two centimetres of the trachea in the loop. After the removal of the needle, he seized one of the threads with two forceps in communication with an electric battery, and made the section of the tissues comprised in the loop without hemorrhage. The trachea being opened, the child coughed violently, and expelled the foreign body which was in the trachea, and for which the operation had been performed. A week subsequently the wound was healed, and the patient well. The first number of the *Archives Générales de Médecine* for 1873 contains a series of eight observations by different operators, the particulars being furnished by M. Bourdon. The operation as performed by M. Verneuil is as follows. There are three steps: the incision of the skin and of the soft parts; the incision into the trachea; and the introduction of the canula. 1. After having marked with the nail the point which corresponds to the inferior border of the cricoid cartilage, the extremity of the blade of the instrument is passed in and made to cut downwards to an extent corresponding to the diameter of the canula that is desired to be introduced, and the thickness of the soft parts covering the trachea. In the infant, the first incision, which is made with great rapidity, ought not to be made deeper than the skin, lest the trachea should be opened at the outset and there be a risk of cauterizing it, if not of perforating its posterior wall. 2. The trachea being exposed, it should be seen that the wound corresponds to the middle line, and the point of the knife should be made to penetrate into the first interspace between the cartilages and the necessary number of rings divided. 3. The introduction of the canula is the last and easiest of all. This proceeding, it is obvious, differs considerably from that of M. Amussat; but, in view of the difficulties that are presented by the adult when tracheotomy is required, M. Bourdon prefers the latter.

LATENT GONORRHŒA IN FEMALES (Nöggerath: *Centralblatt f. die Med. Wiss.*, No. 49, 1872).—This writer asserts that, as a rule, gonorrhœa remains uncured during the life of the individual once affected, and that the disease may be communicated to another individual even during the period of latency, whether the same last a few months or from one to five years. Hence he thinks that a man who once has had the gonorrhœa almost always infects his wife, and that the *entire host of female ills*, especially incurable perimetritis, inflammations of the ovaries, and sterility, is the result of this contamination.

The writer cites histories of fifty cases, some of which seem to show a connection between the chronic forms of gonorrhœa and certain diseases of women. In other cases, however, the men had been well for many years, and their wives had never complained after their marriage until abortions, normal labors, or instrumental deliveries had taken place.

The writer also lays some diagnostic stress upon a fungus which he says he has found in the latent gonorrhœa of females, and in the secretion of a fresh gonorrhœa.

INOCULATION OF SYPHILIS BY MEANS OF VACCINATION (Eulenberg: *Berliner Klin. Wochenschr.*, Sept. 16, 1872).

At a meeting of the Medical Society of Berlin, Eulenberg expressed the following opinions upon the abovementioned topic:

1. Congenital syphilis can remain latent during the first three months.

2. Syphilis is not communicable by vaccination, if only pure lymph is used.

3. A minimal admixture of blood or scab can be the communicator of syphilis. This has been proven by experiments instituted quite recently by Reiter, in Germany, and Hutchinson, in England.

4. If the conveyance occur by means of blood or scab, it is of no moment whether the vaccination is done by means of a cut or by puncture with a needle.

Reiter, however, has asserted that a conveyance of the virus is impossible with a needle, and can only be communicated by a cut.

5. We may say, not with absolute certainty, but in all probability, that vaccination has an influence in producing a slower progress in the syphilitic trouble.

6. The preservation of the virus in glycerin is worthy of our attention. By this method of treatment the foreign matters connected with the virus are floated off, and the latter will remain behind in the glycerin in the form of a perfectly transparent lymph.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 5, 1873.

EDITORIAL.

SOME SINS OF DRUGGISTS.

STRICTLY speaking, the business of an apothecary is to sell drugs, either on the prescription of a physician or by the orders received from purchasers. To thoroughly qualify himself for so doing, for his own and his customers' best interests, he needs a special education, and a complete acquaintance with chemistry, pharmacy, and pharmaceutical manipulations, drugs, their impurities and adulterations, with the various markets in which he has to seek his supplies, and other details which need hardly be enumerated.

In the pursuit of this business, there can be no question that experience is gained which may be turned to account in the prescribing of medicines as well as in their preparation. New agents may be discovered, or new forms and combinations of remedies already known. Hence the enlightened physician will always be apt to receive and weigh hints on these matters from apothecaries, and to acknowledge the value of such assistance.

But the druggist does not, and cannot, obtain that knowledge of disease and its treatment which alone could warrant his undertaking the responsible office of a prescriber. Still less is he able to do what no physician would venture upon,—to give prescriptions for a whole class of disorders. Hence —and now we come to our first application—the entire system of cough-syrups, alteratives, worm-medicines, and other nostrums (whether backed up or not by well-known names), kept for sale, advertised, or recommended by druggists, is altogether objectionable. At one most respectable store in this city, a large business is done in "Dr. Mütter's Cough Syrup." Would Dr. Mütter have consented during his life to the advertisement and sale of a medicine put up on a prescription of his, as a remedy for "cough"? And is it fair to trade upon his name and reputation, now that he is dead, in a way that he, living, could not have sanctioned? We do not doubt that in some cases this formula may be a very good one; but we insist that it is utterly contrary to ethics and to sound sense to recommend it for the general treatment of coughs, simply because Dr. Mütter occasionally employed it.

Our second point is even a more serious one. A few days since, a prescription of ours for some pills containing quinine was taken to a drug-store on Market Street. When the pills were sent to the patient, the box was wrapped in a paper, within which was also enclosed a circular, setting forth the vast merits of "Dr. Hadley's Great Medical Preparation for consumption, inflammation of the lungs, coughs, colds, sore throat and breast, bronchitis, liver complaint, blind and bleeding piles, asthma, hooping-cough, and diphtheria." A more thoroughly quackish advertisement never came under our notice. The patient asked us if this was a common practice with good druggists. We need hardly say that this prescription, sent to that store by accident, will be the last one of ours that ever goes there.

A good understanding between physicians and apothecaries is extremely desirable, and, in fact, is essential to the best interests of both, and of the public. How to bring it about seems as yet to be an unsolved problem. We fear it will be a long time before the earnest attention and the intelligent action which the subject demands will be bestowed upon it. That something ought to be done, we think the facts now mentioned, with many others before known, afford ample demonstration.

CORRESPONDENCE.

REORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Having repeatedly been requested to express my views respecting the reorganization of the American Medical Association,—a necessity universally conceded,—and believing that the time is at hand when this must be effected or the Association be

abandoned, I respectfully submit, although not without hesitation, the subjoined remarks as the result of my anxious deliberation upon the subject.

It is well known, both to the members of the Association and to the public at large, that since the close of the late war the harmony and deliberations of the Association have been disturbed, at every annual meeting, by the introduction and discussion of topics entirely alien to the real objects of such an assembly. Owing to this fact, the very existence of the Association has more than once been endangered. At the meeting in Philadelphia a year ago, many of the oldest and most prominent members, disgusted with previous proceedings, were ready, in the event of a repetition of difficulties, to withdraw, and to unite themselves into an association founded upon a different basis of representation, convinced that the existing order of things, if persisted in, must speedily bring about the destruction of the Association. They had become tired of these seemingly everlasting questions about the admission of women and negroes, and other matters equally irrelevant and subversive of good order and good feeling. They saw that the constant reopening of such discussions would inevitably have the effect of impairing the usefulness of the Association, and of alienating its members from each other, instead of strengthening, as was the original design of its distinguished founder, Dr. Davis, the bonds of good-fellowship, of promoting social intercourse, and of advancing the best interests of a great and noble profession. They saw that political demagogues, from misguided views and a desire to ventilate their philanthropy, were ready, if they could not accomplish their purposes, to sacrifice the Association, by driving from its ranks those who were of a different mode of thinking. It was for these reasons that the caucus already alluded to was held the evening immediately preceding the meeting in this city last year, the men composing it being determined to secede if, in their judgment, it should appear that longer fraternization upon agreeable and profitable terms should be impracticable. Fortunately, although certain elements of discord were, as usual, introduced, and marked our proceedings, wiser counsels prevailed, and the meeting, apart from these disturbances, was in many respects a most pleasant one, long to be remembered by those who enjoyed the hospitality of this great and beautiful city.

The alterations in our constitution, calculated, in my opinion, to meet these contingencies, are,—

First, the appointment of a medical council, consisting of not less than ten members, a majority of whom shall be residents of the place of meeting, to whom shall be referred all applications for membership, all questions of ethics, and all other business matters, and whose decision shall be final. Such a body, composed solely of wise, judicious, and experienced men, sitting as a kind of court, or board of censors, should hold office for only one year, elect its own president and secretary, and hold quarterly meetings, the last not earlier than two days before the annual meeting of the Association.

Secondly, the Association should consist exclusively of members of State societies, who shall be elected at the annual meetings of such societies; the number of delegates to be optional, but not less, if possible, than twenty-five or thirty. They should hold office for one year, but their attendance should entitle them to permanent membership, and to a vote upon every question in the Association.

If the *outside* affairs of the Association were managed by a properly organized council, such as is here contemplated, the result would be to prevent the introduction of a vast amount of irrelevant and objectionable matter, which, in the existing state of things, is a source of so much annoyance and irritation, and which so greatly interferes with the deliberations of an assembly of a purely professional character. No society of this kind can long survive if it permits the introduction and discussion of political questions. Medical politicians are not fit representatives of the interests of the medical profession. We want no such men among us.

The method of representation here suggested would have a tendency to stimulate the physicians of the country to unite themselves into county and State societies, thereby accomplishing great good in elevating the character of the profession at large, and unifying its interests as a great body of social and scientific men.

One of the crying evils of the Association has been the want of care in regard to the admission of its members. Its doors have swung too easily upon its hinges. While I am, in common with many of our associates, in favor of the widest latitude in this respect, and the strictest observance of democratic principles, we should nevertheless be cautious not to exceed the limits of propriety by the introduction of men not entitled to such a distinction. I have attended two of the meetings of the British Medical Association, and on each occasion I was struck with the fact that the great majority of the members were men who had rendered the profession important services as practitioners, writers, or teachers.

I have long been of opinion that the physicians of the place of meeting of the Association should not be taxed with the expenses of a public entertainment; and to relieve them of this burden, for such undoubtedly it is, I suggested, many years ago, that there should be, on the evening of the third day of the meeting, a public dinner, to which every member who chooses should be admitted on the payment of five dollars. This is the custom of the British Medical Association, and there is no reason, so far as I can discover, why a similar practice should not obtain on this side of the Atlantic. A resolution to this effect was, at my instance, adopted with great unanimity by the Association a few years ago; and, although it has not been rescinded, I have not been able to learn why it was not carried out by the committee of arrangements at the meeting here last May.

There will always be prominent and liberal-minded citizens at the place of meeting who will be glad to entertain the Association at their private dwellings, and will do all they can to make the time of the members pass

pleasantly during their sojourn among them. Last year the houses of several of our most wealthy and esteemed physicians were thrown open to the Association; and there has not been a meeting since the foundation of the Association in which a generous hospitality on the part of our profession was not a marked feature of the occasion.

I have said nothing in this communication respecting the representation, in the meetings of the Association, of our medical colleges, hospitals, and various eleemosynary institutions: let them, by all means, be seen and heard, but let them enter through the common door; as the rest of the medical profession,—the State Medical Societies.

I have the honor to be, very respectfully,

Your friend,

S. D. GROSS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

MR. EDITOR,—I notice in the number of the *Medical Times* for February 8 that "the Trustees of the Presbyterian Hospital, being desirous to extend their benefits to the poor of West Philadelphia, have established a Dispensary on Thirty-ninth Street," and have appointed a physician and surgeon to fulfil its duties and hold daily clinics. Not long ago the Pennsylvania Hospital established an out-patient department, and appointed a staff of physicians and surgeons for gratuitous services.

Now, Mr. Editor, if all these advantages were for the benefit of the really poor, no one would have any right to question the heaven-born charity which prompted the generous trustees to establish them; but is it not notorious that ninety-nine hundredths of the patients seeking their aid are able to pay a respectable physician a reasonable fee? If this be true, is it not a great wrong to the mass of struggling physicians who are striving with might and main to earn a decent livelihood, and to shelter and support those depending upon their exertions, by giving such free access to medical advice? Every profession and trade protects its own members, save the medical. How many clergymen are willing to preach gratis who have no other resource for a living? And how many lawyers are there to be found who are willing to be such good Samaritans? As to the trades, has not every branch of mechanical work its trades-union, which not only will not permit its members to do any work gratis, but punishes them if even they are willing to work for less wages and hours than they dictate? Even the servant-girls have a kind of free-masonry among them, which will not permit them to accept minimum wages.

Why is it the medical profession should stand alone in this matter? or *cui bono* should they seek to go farther, and assist at every dispensary and out-patient department to take the bread out of the mouths of their less fortunate professional brethren? Is it not common to observe that most of the patients who flock to the clinics of the University of Pennsylvania and the Jefferson Medical College are well dressed, being frequently encased in silks and broadcloths, and, to judge by their appearance, abundantly able to pay a respectable physician? And the same is true of the out-patient departments and dispensaries with which our city abounds. Not long ago I was summoned at night to dress the hand of a lieutenant of police, who was wounded in arresting a prisoner. Not seeing my patient for several days, I concluded he was under the care of another physician. Meeting him on the street a couple of weeks after the accident, I asked him how he was getting along; his reply was that his wound was not doing well, and *that he was under treatment at the Presbyterian Hospital!* Here was a man receiving not less than one hundred dollars a month getting surgical aid gratis!

Now, how long will it be before *another* advance is made, and a staff of physicians and surgeons appointed to visit regularly at their homes any persons who may desire to avoid paying a physician for his services?

I might be called on, as I have made my complaint, to suggest a remedy; but this I conclude is the duty of the philanthropist, and where the *really poor* are concerned no difficulty need be found to insure them the best medical advice gratis. The difficulty lies in separating the sheep from the goats; and surely the experience of medical men will enable them to detect the bogus from the genuine. I wish it to be understood that I am not opposed to the establishing these dispensaries and out-patient departments, but that the unmeasured and gratuitous advice should cease to those who it is plain seek such establishments to avoid paying for medical services.

It is well known among us that, *nolens volens*, every physician in much practice is obliged to give his attention and advice to very many persons without even receiving thanks therefor, and, to the eternal praise of the profession be it said, they are few and far between who begrudge their labor in so doing; but it is evident that, such being the case, in the multiplying of numerous dispensaries and out-patient departments there will be little left to a

STRUGGLING PRACTITIONER.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, FEBRUARY 27, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. JAMES TYSON exhibited a specimen of *cancer of the pylorus*, removed from an old gentleman aged 72 years. The case was interesting in the history of its progressive development, beginning apparently about the 1st of September, 1872, with symptoms of slight discomfort in the epigastrium, which, though temporarily relieved by treatment, became gradually worse. For two or three days at a time, until about November 1, relief would be almost total under the use of bismuth and morph. sulph. At this date, however, the feeling of discomfort became one of positive nausea, though

without vomiting; this was at first attributed to the opiate, but was found to persist on its discontinuance. So a constipation which gradually supervened, and to which he was previously altogether a stranger, was also supposed to be due to the same cause, but failed to disappear on discontinuing the remedy. For some time afterwards, however, the bowels were easily moved by mild cathartic remedies.

About the 1st of November he began to complain of curious brief spasmodic attacks of pain, which appearing to begin at the epigastrium would rapidly rise to the fauces, suggesting in its whole movement the phenomena of a hiccough. These attacks, but occasional at first, increased in frequency and severity until they occurred at intervals of less than an hour and caused extreme suffering. At this time also, November 1, palpation conveyed to the finger a sense of resistance at a point in the median line about midway between the epigastrium and umbilicus. Percussion, however, gave no distinctive information, and there was no tenderness on pressure. Extreme pallor was now also promptly noticed by strangers, and close examination revealed progressive emaciation, although he continued up to this date, and indeed to December 1, to go daily to his place of business.

Opium combined with belladonna effectually checked the paroxysmal pain, and though the attacks occasionally returned with great severity, they were generally promptly controlled by an increase in the quantity of anodyne, or by a hypodermic injection of $\frac{1}{6}$ grain of sulphate of morphia.

The obstinate nausea, however, persisted with little or no abatement, notwithstanding a careful trial of all the usual and unusual remedies, including the monobromate of camphor. Morph. sulph. and bismuth. subnit. were by far the most efficient remedies. Indeed, for a time relief was so great that there was hope that the diagnosis was mistaken. Notwithstanding these symptoms of nausea, he vomited seldom, until a short time before death,—perhaps two or three times in the month of January. Constipation, however, became obstinate, and for at least eight weeks before death his bowels were very seldom open without the use of injections. By February 1, emaciation had so far progressed that the outlines of a tumor were distinctly discernible by palpation, still in the median line as above described. Percussion gave distinct evidences of the existence of a tumor in the same situation, and the pulse of the aórta contributed to it a pulsation; there was a distinct upheaval with every systole of the ventricles. Food now had to be administered altogether in the liquid form, and in very small quantities in order to secure its retention; and even the smallest quantities were vomited. There was never, however, vomiting of blood. There was no disposition to take food,—no hunger whatever; and for four or five days before death almost nothing was ingested. He died Saturday, the 22d of February, 1873.

A post-mortem examination forty-two hours after death revealed a firm scirrhous mass surrounding the pyloric orifice, and so far encroaching upon its lumen as to permit the passage of the little finger only with extreme difficulty. No other organs were involved. There was apparently no erosion of the mucous membrane at the pylorus.

Remarks.—The situation of the tumor,—in the median line midway between the umbilicus and the epigastrium,—together with the imperfect development of gastric symptoms in the early stage of the disease, led me to suspect that the pancreas was involved, and perhaps the primary seat of the disease, an opinion in which Dr. Da Costa, who saw him in consultation, concurred. The administration of oil, however, was not followed by its appearance in the stools.

The PRESIDENT remarked that in his experience with cases of cancer of the pylorus he had also met cases in which the tumor was in the median line, but that he had also met very large tumors with dulness corresponding in position to the normal situation of the pylorus.

The specimen was referred to the Committee on Morbid Growths, who reported it to be a "specimen of *scirrhus ventriculi*, which involves the mucous and submucous layers of the stomach. The amount of dense white connective-tissue stroma strongly predominates over the cellular elements, which are of small size, yet having distinctly the epithelial type, and generally arranged in long tubuli, as though they had originated in the ducts of the mucous glands."

Dr. J. EWING MEARS presented a specimen of *cystic myxo-sarcoma* removed, post mortem, from a patient of Dr. O'Hara, aged about 50 years. It formed a large mass, estimated to weigh between forty and fifty pounds, occupying the abdominal cavity, and with no discoverable attachment. An interesting feature in connection with the case was that the patient had within the past three years been relieved of two sub-mucous fibroid tumors of the uterus, one spontaneously, while the second was removed by Dr. O'Hara, after having partially passed through the os.

Dr. Mears thought that the tumor exhibited may at one time have been a pedunculated fibroid tumor of the uterus, developing into the abdominal cavity, and that the pedicle, becoming much attenuated, was finally detached; while the tumor itself continued to be nourished by the adhesions which had formed not only to the parietes of the abdominal cavity, but also to the adjacent viscera.

The specimen was referred to the Committee on Morbid Growths, who reported as follows:

"Your committee, having examined the colossal abdominal tumor presented by Dr. Mears, beg leave to report that they consider it to be a myxo-sarcoma.

"Different histological elements were found to exist in different portions of the growth. The prevailing structure, however, is the sarcomatous, with its large, round, nucleated cells: these are imbedded in a delicate network of fibrillated interstitial substance. A few giant cells, containing eight to ten nuclei, were also observed.

"At other points, where the growth assumed a softer, semi-transparent, jelly-like consistence, the prevailing structure is myxomatous, with its stellate anastomosing cells, imbedded in a hyaline substance that is rendered cloudy upon the addition of acetic acid.

"From the microscopic appearances alone, and from the meagre post-mortem records furnished to the committee, they are unable to determine whether this growth should be regarded as originating from the uterus, or whether it may not be a myxomatous degeneration occurring in a tumor of the omentum.

"Klebs, who has examined a number of immense and rapidly-growing abdominal tumors closely in every respect resembling this specimen, states that they are, as a rule, either lympho-sarcomata of the mesenteric glands, or myxomatous degenerations of lipomata of the omentum."

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

MARCH 3, 1873.

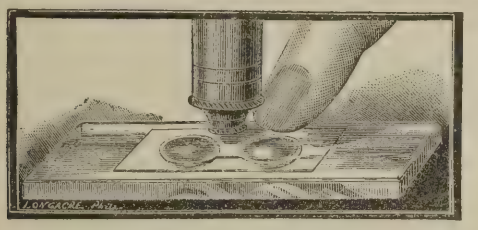
DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

PRESENT,—Drs. I. Norris, Stellwagen, Tyson, Leconte, Trueman, Richardson, and Messrs. Betts, Warner, and Corlies.

Visitors,—Dr. Thomas Penrose, U.S.N., and Mr. Holman.

The report of the committee upon Dr. James Tyson's paper on the Microscopic Study of Blood and Epithelium, recommending it for publication in the *Philadelphia Medical Times*, was read and adopted.

Mr. D. S. HOLMAN, Actuary of the Franklin Institute, on invitation from the Director, Dr. RUSCHENBERGER, exhibited his Improved Glass Slide for Microscopes, and explained its construction and mode of manufacture.



This slide is composed of the usual slip of glass, such as is ordinarily used by microscopists; but, instead of the customary plain surface, two concave depressions are ground in the upper side (see figure), and connected by one or more shallow canals, carefully cut in such a way as to present on transverse section a gradually increasing depth up to about $\frac{1}{100}$ of an inch. In using this slide each excavation is to be partly filled with the fluid under inspection, and the remaining space in each is to be charged with common air; the large thin glass cover being applied so as to seal up both cavities and the communicating canal, over which it will be retained (as stated by Mr. HOLMAN) by atmospheric pressure alone. In this way is secured what the inventor terms a double *thermal pressure chamber*, either division of which can be made to emit a minute portion of its contents through the delicate canal and pass the same into the opposite depression, by means of the sensible heat radiated from a single finger of the operator brought near it for that purpose. The most complete control is thus obtained over even a single red blood-corpuscle, which may be arrested in the canal, held stationary under observation, and actually turned over in the focus.

The action of this ingenious piece of apparatus was tested by several of the members present, who united in bestowing upon it their hearty approval.

Mr. JOHN WARNER inquired why the fluid in the communicating canal did not run down into the concavities on either side of it, which certainly admitted of its flowing to a lower level.

Mr. HOLMAN replied that it was on account of the force of capillary attraction, which caused the liquid always to occupy the smaller crevices, whilst the air-bubble filled up the larger space; just as water would pass through a much more minute opening than air would do, because of the power of attraction for the liquid possessed by the sides of an aperture.

Dr. ISAAC NORRIS remarked that he believed some modification of this admirable contrivance would prove most useful to scientists as an extremely delicate differential thermometer, since the ball of the finger, even when held at a distance of two or three inches from the cavity on either side of the fine canal upon the slide, would actually give off enough radiant heat to expand the air-bubble nearest it, and so cause a rapid current of blood-corpuscles along the narrow channel beneath the microscope-lens. Of course for this purpose some modification in the shape of the apparatus might be necessary, but the important principle involved would still remain the one he now advanced,—namely, the application of the microscope to the detection and observation of those minute currents resulting from expansion of the air occupying either cavity, in consequence of an almost infinitely small rise in temperature, as compared with that of the other side. Dr. NORRIS thought the "Holman's improved moist chamber and current cell," as he hoped it would always be called, must likewise prove of great service in studying the phenomena of crystallization; as, for example, when crystals were formed under the eye of the microscopist, by double decomposition of two solutions contained in the excavations of the slide and cautiously mixed together in the delicate canal which united them.

Dr. JOSEPH G. RICHARDSON observed that some months since, in endeavoring to investigate the changes undergone by human blood preserved for several days without desiccation, he had felt the need of such a piece of apparatus as that now exhibited by Mr. Holman, and had contrived a slight modification of Stricker's moist cell, which, however, in most cases would be far inferior to the very ingenious slide now on the table. His improvement of Stricker's putty cell enabled the observer to examine a fluid without being obliged to retain his microscope in the inconvenient perpendicular or German position, and consisted in a small glass cover about half an inch in diameter, upon which a minute drop of blood, for instance, was to be placed, and a larger cover about one inch across. This latter was to be laid upon the little one, which would adhere to it, and remain attached with a film of blood between when transferred to a slide and pressed down gently upon a ring of putty, as directed by Stricker in his excellent Manual of Histology.

Mr. HOLMAN, in reply to a question, said that a drop of blood the size of a pin's head was large enough for examination, all that was required being that we should have enough fluid to fill up the little canal and make a very narrow rim of liquid around the edges of the two cavities it joined. He believed that physicians would find the apparatus very useful for collecting, at a distance from home, specimens of blood, pus, cancerous discharges, etc., for microscopic examination several days afterwards.

Dr. TYSON inquired upon what part of the slide the drop of fluid was to be placed when preparing a specimen for preservation and subsequent investigation.

Mr. HOLMAN answered that he had found it advisable to apply the drop to the middle of the canal, and allow it to flow down on each side into the excavations, either before or at the moment of laying on the thin glass cover.

Dr. RICHARDSON asked how long Mr. Holman had found that blood-corpuscles, cancer-cells, etc., would remain unaltered when prepared in this way for examination.

Mr. HOLMAN remarked that one specimen of blood upon the table had been thus mounted six days previously, and that the only change observable was the alteration of some of the red corpuscles from a biconcave to a spheroidal shape.

On motion of Dr. TYSON, it was unanimously resolved that the thanks of the Section be tendered to Mr. Holman for the very great favor he had conferred by exhibiting his ingenious moist slide to the members this evening.

REVIEWS AND BOOK NOTICES.

LESSONS IN PHYSICAL DIAGNOSIS. By ALFRED L. LOOMIS, M.D., Professor of the Institutes and Practice of Medicine in the Medical Department of the University of New York, etc. New York, William Wood & Co., 1872.

These lectures were first published at the request of Prof. Loomis's classes in physical diagnosis, and now

appear in a third edition, revised, and with the addition of five new "lessons,"—three on the examination of the urine, and two on the mechanical aids to diagnosis.

The method of teaching adopted by the author is simple, and he has generally made himself clear and readily understood.

The first two sections are on the examination of the lungs and heart, and are calculated to give the beginner great assistance in the study of these organs in health and disease. This is the best portion of the book, of which it occupies more than one-half.

The physical examination of the abdomen is next taken up. It is impossible to write a complete treatise on diagnosis as applied to the abdominal organs without going at length into their pathology; which, of course, could not be done in a work of such brief limits as this. A short description, however, is given of the anatomy and morbid changes which occur in these viscera; but, owing to its want of completeness, the reader will, we fear, receive some erroneous impressions.

For instance, we are told that in cirrhosis of the liver there is contraction of this organ. This is certainly true of the latter stages of the disease; but we are not informed of what is taught by most authorities,—that in the beginning there is enlargement of the liver, sometimes to a very considerable extent.

No reference is made to *ballottement* in the rules which are given for the diagnosis of pregnancy. This is a most valuable aid to diagnosis in the early months of pregnancy, and may certainly be considered a means of physical examination.

In the lessons on the examination of urine its physical properties are first considered; then the apparatus employed, and some of the tests for albumen, sugar, etc., are described. Directions for the quantitative analysis of the urine are given, and one lesson is occupied with the microscopical appearances of urinary sediments and their clinical significance.

The last two lessons are on the "mechanical aids to diagnosis." Descriptions and illustrations are given of the various instruments employed, as well as instruction in their use.

The desire for brevity in the composition of this work has in some instances caused obscurity, and there are frequent evidences of careless writing. The subjects are freely illustrated with wood-cuts, some of which, however, are poorly executed. Several of the cuts in the lessons on the heart and lungs are copied from Da Costa's Medical Diagnosis, and others which are not acknowledged as coming from this source bear a striking resemblance to some in the same work.

On the whole, we can cordially recommend the book to the profession at large, but it is especially adapted to the requirements of students and recent graduates.

MEDICAL ESSAYS. Compiled from Reports to the Bureau of Medicine and Surgery, by Medical Officers of the Navy. Published by Order of the Navy Department.

It has often been a matter of surprise to us that the medical officers of the navy, many of whom are gentlemen of superior abilities, having ample opportunities of observing and recording interesting cases, have not contributed more to the medical literature of the country. Visiting and mingling with the various nations of the world, a man of close observation can surely see something either in the way of diseases little known to us, or new methods of treatment, an account of which would be of interest to the medical world.

We hail the book before us as a harbinger of better things. It is made up of a number of reports made by various surgeons to the Bureau of Medicine and Surgery, arranged in book-form by Dr. A. L. Gihon, who himself contributes the *pièce de résistance* in the form of an essay on Naval Hygiene.

The doctor gives us a plain, practical, common-sense view of this very important subject; and although his book is not so large nor does it go so much into detail as the justly celebrated work of Fonssagrives, yet in many respects we like it better, principally because it is better adapted to our own service than is that of the French author.

That this work will meet the consideration it deserves from those in authority, we scarcely dare hope. So apt is the progressive surgeon to be looked upon as an innovator and an overturner of established things, and so powerful in the minds of many officers are those cabalistic words, "usages of the service," that we fear that many of the abuses that now afflict the service will continue to exist until the superior education now given the younger officers of the navy will have the effect of dispelling some of the old Benbow notions that still lurk in the craniums of our old sea-kings.

As the book was written more especially for the instruction of the younger members of the corps just entering the service, it very properly begins with a chapter on the "examination of recruits." This duty, according to the author, is often carelessly performed, very much to the detriment of the service; especially was this the case during the late war. The rules which he lays down will make the examination searching and thorough. The only fault we have to find (if it be a fault) is, that any man who can meet all the requirements can make more money by sitting as a model to a sculptor than in serving his country for eighteen dollars a month: however, in these piping times of peace, we can afford to be more strict, as but few men are wanted and plenty offer.

The receiving-ship, navy-yards, humidity, ventilation, light, clothing, cleanliness, food, water, sleep, exercise, climate, moral influences, and the sick-bay, are all ably discussed, and many excellent suggestions made and abuses exposed. As an instance of some of the things that want reforming, we give one example. The crew of a man-of-war are served all their meals inside of eight hours, viz., from 8 A.M. to 4 P.M., and fast sixteen hours, although their most arduous duties are often performed within that period. This is all wrong, and could easily be remedied if those tiresome sayings, "usages of the service," and "they do it in the English service, you know!" could only be lost sight of.

We regret that want of space prevents us from going more fully into the merits of this excellent work. It will commend itself to the good sense of every enlightened medical officer, and if those in authority will only act upon some of the suggestions made by the doctor, poor Jack will have good cause to be thankful to him. In speaking as we have done, we do not mean to reflect upon navy officers as a body. A large majority of them are men of sense and good judgment, and are always ready to act upon a good suggestion coming from a medical officer; but there are a few, we regret to say, who, puffed up with authority, are a little too tenacious of their privileges, and fearful of their jurisdiction being encroached upon,—men who would fain run the sick-bay as well as the ship.

Medical Inspector Shippen contributes a very interesting "report upon certain English hospitals," and a "Schedule of Examinations at Netley." We believe this article was published for the purpose of calling the attention of the authorities to the necessity of establishing an institution similar to the Netley Hospital School for the purpose of training candidates who have passed their examination before the army and navy boards, previous to entering upon active service. None but the initiated know how important this is; but want of space forbids us enlarging upon this subject.

The rest of the book is made up of a Report of a Resection of Head of Femur, by Surgeon W. E. Taylor;

two reports on Yellow Fever, by Surgeons Bloodgood and Pilcher; a report on the sanitary condition of the Asiatic squadron, by Medical Inspector R. T. Maccoun; an interesting case of Diabetes, by Medical Director J. McClelland; a case of erosion of the entire penis, by Dr. W. S. W. Ruschenberger; and a report upon the charitable institutions, hospitals, and peculiar diseases of Peru; all of which are of considerable interest, and go to show that the medical officers of the navy are waking up to the necessity of showing their brethren on shore that they are what they are,—worthy representatives of a noble profession.

THE TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK, for 1870. Albany, 1871. Ditto for 1871.

These two handsome volumes, comprising the proceedings of the largest and perhaps most prosperous of our State medical societies, have reached us so nearly together that we must include both of them in a single notice.

The Transactions for 1870 have for their frontispiece an excellent likeness of the late Prof. Alden March. Farther on in the volume we note an elaborate paper on the Endoscope, illustrated with chromo-lithographs, by Dr. Robert Newman; a short notice of the value of chlorate of potassa in serous effusions, by Dr. Samuel Peters; an instructive article on the luxation of the ulna accompanying Colles' fracture, by Prof. E. M. Moore, of Rochester; and an account of twelve cases of trichiniasis, by Dr. Thomas M. Flandrau, of Oneida County; besides several other valuable monographs, which want of space alone prevents us from referring to more in detail.

The volume for 1871 has its place of honor most worthily occupied by the able address of the president, Dr. S. O. Vanderpoel, upon Pathological Anatomy, the necessity of its study, and its influence upon medicine as a positive science. This discourse is succeeded by several interesting papers of minor importance, among which the prize essay of Dr. Durant, of New York, is remarkable for the absolute ignorance it displays in regard to the observations of Niemeyer, Waldenberg, and Cohnheim respecting the origin of tubercle and its relation to cheesy deposit; and following these we have a dissertation on insanity and its dependence on physical disease, by Dr. John P. Gray, Superintendent of the State Lunatic Asylum at Utica, whose wide opportunities for investigation here bear fruit in a deeply thoughtful paper, in full unison with the progressive spirit of our age.

Another prize essay, by Dr. S. Fleet Speir, describes that important surgical appliance, the artery-constrictor, and is illustrated by eight plates. Dr. St. John Roosa furnishes an instructive statistical report on nearly five hundred cases of diseases of the ear; Prof. L. A. Sayre, an account of his ingenious vertebrated catheter; and Dr. T. Addis Emmet and Dr. N. Bozeman, articles respectively upon some gynæcological subjects in connection with which their names are well known to medical men.

Altogether, the Transactions for 1870 and 1871 contain a mass of new facts and carefully-drawn conclusions, which forms a real and substantial addition to our science, and as such afford the profession a contribution of printed knowledge whereof any medical society may well be proud.

COLD BATHS IN RHEUMATIC FEVER.—Dr. Sydney Ringer, in *The Practitioner*, reports the case of a girl æt. 22, in whom rheumatic fever was treated by means of cold baths, and by the application of large-sized ice-bags, with evident benefit and an entirely successful result.

GLEANINGS FROM OUR EXCHANGES.

TRANSPOSITION OF THE VISCERA (*Irish Hospital Gazette*, March 15).—Dr. Nixon recently exhibited to the Pathological Society of Dublin a very remarkable instance of complete transposition of the viscera, taken from the body of a boy, aged about 15 years, who died of recent double pleurisy with effusion, half an hour after admission into the Mater Misericordiæ Hospital on March 7. No history of the case was obtained. The following, among other alterations in the normal anatomy of the several parts, were observed. The heart was directed to the right side; the arch of the aorta passed from left to right, crossing over the root of the right lung; thence the vessel continued its course through the posterior mediastinum, lying to the right side of the œsophagus. The arteria innominata passed upwards and forwards to the left sterno-clavicular articulation, where it divided into the left carotid and left subclavian arteries. The superior vena cava passed in front of the root of the left lung. The left lung had three lobes; the right but two. The right pneumogastric nerve passed over the arch of the aorta, giving off the recurrent laryngeal, which ascended in the groove between the trachea and the larynx. The left pneumogastric supplied the posterior surface of the stomach; the right, the anterior. The liver occupied the left hypochondriac region, its greater lobe being on the left side. The œsophagus passed downwards to the right side, and the cardiac extremity of the stomach and the spleen occupied the right hypochondrium. The head of the pancreas, the cæcum, and the sigmoid flexure of the colon, etc., occupied exactly opposite positions to those which they normally do, and the vessels and nerves of the abdominal cavity were also misplaced.

HYSTERICAL ISCHURIA.—M. Charcot, in his opening lecture at La Salpêtrière (*Ann. et Bul. de la Société de Gand*, July, 1872), gives an account of an extraordinary case of suppression of urine. A young woman, subject to various manifestations of hysteria, and bedridden, began in the month of April, 1871, to experience a remarkable diminution of the urinary secretion. Careful watching placed the reality of the symptoms beyond a doubt. The woman experienced daily attacks of vomiting, and in the fluid thrown up a considerable quantity of urea was found. At the end of several months, the ischuria gave way to a slight polyuria, at which time all vomiting ceased. This was followed in 1872 by another period of diminution of the urinary secretion, this time without suppression, the vomited matter being less abundant than before.

The blood was found, upon examination, to contain no more than the usual amount of urea, so that it must be admitted that the production of this constituent was much below the normal amount.

M. Charcot proceeds to show at length that in the present instance the retention of urine was not dependent on a spasm of the ureter, for where the canal of the ureter is obstructed, either by means of a ligature or by the presence of a calculus, the urine, while it is secreted less abundantly, becomes very weak, which was not the case with this woman: so that the cause of the ischuria must have had its seat in the kidneys.

This case will serve to demonstrate that hysterical ischuria has an actual existence, a fact which has been very generally doubted, so many spurious cases of this affection have from time to time made their appearance. It is not unreasonable, therefore, to regard the hysterical vomiting, which takes place when ischuria is present, as a supplementary process to the functions of the kidneys.

Wound of Spinal Column and Cord (*Irish Hospital Gazette*, March 15).—At a recent meeting of the Surgical Society of Ireland, Mr. H. G. Croly detailed the history of the case of a boy, aged eight years, who, while playing in bed with a steel rib of an umbrella, fell on to the floor, one of the ends of the rib being in his mouth at the time. The rib went deeply into the back of the pharynx, and was pulled out by the child himself. He vomited and bled from his mouth and nose. That night he raved, and his mother stated that he had double vision. He was admitted into hospital on the 12th of February, three days after the accident. There was then a punctured wound visible at the back of the pharynx, on a level with the lower border of the velum; the boy tottered on his limbs; he had convergent strabismus, knit brow, was intolerant of light, and had marked febrile disturbance, his temperature being 102.5°. He had also difficulty of swallowing; he whistled, screeched, and threw back his head, and held his neck very stiff. From these symptoms, Mr. Croly diagnosed that the umbrella-rib had penetrated the spinal cord. His head was shaved and ice applied, and he was leeched at each side of the spine; calomel and James's powder were also administered. On the 14th of February his temperature fell to 98°, and the boy has now quite recovered. Mr. Croly had ascertained on the dead subject that an instrument resembling an umbrella-rib, passed directly backward in a position corresponding to the wound of the pharynx in this case, penetrated the spinal column between the first and second vertebræ. Mr. Croly was not aware of any similar injury having been recorded.

Syphilitic Boulimia and Polydipsia (*Archiv für Dermatologie und Syphilis*, October, 1872; from the *Gazette des Hôpitaux*).—Fournier states that within the last few years he has observed about fifty cases of boulimia and polydipsia due to syphilis. In the majority of cases the condition came on with the first constitutional symptoms of syphilis. It was noted to be of much more frequent occurrence in women than in men, and to have existed particularly among individuals of nervous and irritable temperament. It generally occurred in connection with other nervous symptoms, such as headache, drowsiness, neuralgia, analgesia, etc. The boulimia came on suddenly, often in the course of a night, and the patients were noticed to eat twice their regular amount of food without satisfying hunger. Unquenchable thirst was also generally present at the same time; this symptom, indeed, rarely existing without the boulimia. This singular condition, as a rule, remained but for a short period, varying from a few days to as many weeks, though in one or two cases it lasted, with remissions and exacerbations, for months. When we have boulimia it is always a sign of a severe syphilis, and calls for energetic treatment. Without expressing positive views, Fournier is inclined to regard these phenomena as neuroses.

Effect of Cold on Frogs (*British Med. Jour.*, February 22).—Dr. Horvath, of Kiew, has investigated the question, to which various answers have been given, whether frogs can be restored to life after having been frozen. He finds that a temperature of 23° Fahr. kills the striated muscular fibre, so that when thawed it does not contract under either a mechanical or an electrical stimulus; and hence he infers that, in the cases where revival is said to have taken place after subjection to a temperature of 5° Fahr. (Von Humboldt), or 14° to 19.5° Fahr. (Kühne), the temperature of the muscles was not reduced to the extent supposed. The heart of the frog, freshly removed and frozen hard, contracted rhythmically for some time after being thawed. The iris, which in rabbits is always dilated when a certain amount of cold is reached, in frogs undergoes contraction during the cooling process, and becomes dilated again under warmth. The contraction, sometimes to the size of a pin's head, and the succeeding dilatation, may be readily observed in the same animal under alternate applications of cold and heat. Dr. Horvath agrees with Pouchet that the blood-corpuscles are destroyed by freezing; but he does not think that they exert any poisonous influence when thus spoiled.

Treatment of Typhoid Fever.—*The Practitioner* for February quotes from the *Journal de Médecine* the following as the treatment of typhoid fever adopted by M. Péter at La Charité. Every other day he gives a glass of Seidlitz-water, and morning and evening an emollient injection. The injection he considers to be useful in removing putrid matters. The glass of aperient fluid, without exhausting the patient like a daily purge, also keeps the intestinal canal clear from disintegrated matter. He uses the sulphate of quinine in quantities amounting to from seven to fifteen grains per diem as a febrifuge, increasing the dose in proportion to the intensity of the attack. He places great reliance on alcoholic stimulants, prescribing every day four or five ounces of quinine wine, which is made into a lemonade so as to make from two to three pints of fluid, by which means the vegetable acids are freely and easily administered. These, he thinks, remove the crusts of the tongue, and the symptoms produced by putridity are relieved. He uses sponging with vinegar, instead of baths or cold affusion, once daily.

Phonometric Examination of the Chest and Abdomen (*British Medical Journal*, March 8).—Dr. Guttmann has investigated the merits of a method of physical examination recommended some months ago by Dr. Baas. It consists simply in applying an ordinary tuning-fork to the chest or abdomen, and noticing the modifications of the tone produced by the part struck. The application may be made either directly or through a plessimeter; the latter, of course, being the more pleasant to the patient. The general result of Dr. Guttmann's observations is, that the use of the tuning-fork is inferior to ordinary percussion in cases of chest-disease; while, in regard to the abdomen, the only morbid conditions which it indicates are ascites, tumors, etc., which can quite easily be made out by manual palpation. The recommendation of Dr. Baas is, we believe, however, not original. The same principle was advocated, we think, in a London contemporary a few years ago.

Cæsarean Section on the Dead Body (*British Medical Journal*, March 8).—A case of post-mortem Cæsarean section occurred in the Vienna General Hospital last month. A woman, aged 36, was admitted on February 6, in an advanced stage of pulmonary consumption, she being at the time seven months advanced in pregnancy. She died on the 12th; and the Cæsarean section was at once performed by Dr. Blumenfeld, in the presence of Dr. Standthartner, under whose care the patient had been. The operation was commenced seven minutes after the death of the mother, and lasted scarcely three minutes; a living child, about seven months old, was removed, and died in three hours and a quarter.

Monstrous Birth (*British Medical Journal*, March 8).—A case of monstrous birth is reported as having recently occurred at La Olmeda de la Cuesta, in the province of Cuenca in Spain. There were two heads, a single trunk, and four legs. One of the heads was still-born,—apparently from injury received during the labor; the other lived two hours. The preparation is to be deposited in the Anatomical Museum in Madrid.

Ergot in Phthisical Hæmoptysis.—Dr. Anstie, in *The Practitioner* for February, 1873, details some cases in which the fluid extract of ergot, in forty-minim doses, produced a marked effect in diminishing the amount of blood brought up by patients laboring under phthisis, in various stages.

In his paper, which is to be continued in another number, he proposes to compare the benefits obtained from ergot with those from gallic acid, acetate of lead, digitalis, turpentine, and alum.

At a recent meeting of the London Pathological Society, great interest was excited by specimens of new hæmatozoa from the human blood, which had been sent by Dr. Lewis of the Indian Medical Service and Dr. Lamprey of Hong-Kong, through Dr. Parkes of Netley. A long and interesting discussion ensued, in which Dr. Cobbold, Dr. Bastian, Dr. John Harley, and others took part.

MISCELLANY.

Polyclinical School at Pesth.—The *Wiener Med. Presse* of February 2 quotes a letter dated Pesth, January 29, asserting on good authority that a "Poliklinik" will be put in operation in that city in March of this year. "The fact," the writer goes on to say, "is not in itself new, but those concerned in the matter have kept it so secret that to this day, even in medical circles, there is scarcely any one who knows of it. A brief history of the Poliklinik is as follows: As early as the end of year before last, shortly after the erection of the Poliklinik in Vienna, some of the teachers in the Medical Faculty here decided to have one like it, and were strengthened in their plan by seeing the rapid strides made by the Vienna school. On making application to the Minister of the Interior for permission, they were told that not only was there no objection to the establishment of the institution, but that he (the minister) would hold himself ready to aid the plan by all the means at his command. The city authorities favored it also. Arrangements were now made by which Dr. Faludi, the physician of a hospital where about 2000 patients were treated yearly, consented to merge his institution in the Poliklinik, and to become the lecturer on children's diseases in the latter." The other teachers will be Gebhardt, Kétli, and Stiller for internal diseases; Schwimmer for dermatology; Böke, otiatrics; Siklóssy, ophthalmology; Löri, laryngoscopy; Kesmarszky and Hasenfeld, gynæcology; and Verebélyi, surgery.

Singular Case.—The following account comes from the secular papers: A man giving his name as Theobald Fahre, a native of Kehl, in Baden, was found recently in a deserted negro cabin near Augusta, Ga., with his throat cut from ear to ear, and both the œsophagus and trachea completely severed. As nearly as could be ascertained, he had lain there for six days in that condition, without nourishment of any kind. He was carried to the city hospital at Augusta, when the terrible wound was sewed up, and he is now recovering. Fahre, in accounting for the wound which he bears, was somewhat incoherent and unsatisfactory in fixing the responsibility for the deed. On one occasion he said that while travelling along the road at night he was suddenly attacked by two men, knocked down and his throat cut, as previously described, and that he was unable to tell whether they were white or black men. On another occasion, he said that while travelling the road in daylight he was ordered to halt by a white man. Not obeying the order, he says that the man rushed upon him, and cut his throat, leaving him lying in the road.

Under existing circumstances, it would seem to be altogether legitimate to infer that the sufferer, in a moment of temporary mental aberration, probably caused by a lack of knowledge of his whereabouts, had himself inflicted the wound in an attempt to commit suicide.

False Teeth.—According to the *British Medical Journal*, these caused the death of Cuvier, and were a source of discomfiture to Lord Brougham.

Cuvier, impatient at the interruptions of that perpetual interrupter, M. Glais-Bizoin, in the National Assembly, rose so impatiently to answer him, that he jerked his teeth out on the floor, and, stooping not less precipitately to pick them up, fell head-foremost, and struck his head against the floor so heavily as to give rise to the illness which proved fatal to him. M. Glais-Bizoin, then a very young man, promised himself to abstain from his fatal habit of incessantly interrupting; but he was incorrigible.

Lord Brougham, in the course of the proceedings of a great meeting of the Social Science Association, of which he was president, was stopped in the middle of a speech by his teeth falling out. After groping on the floor, and on presently resuming his speech, he made the best of the incident by observing, "Our teeth are sources of trouble from infancy to old age."

Obstetrical Museum.—The Philadelphia Obstetrical Society has issued a circular announcing its intention to establish a museum for the collection of deformed and distorted pelves, and for the preservation of obstetrical instruments possessing historical value or illustrating new methods of treatment. Casts or photographs are solicited of such specimens as cannot be sent; and in special cases the Society will offer a pecuniary recompense, if desired.

Space has, we believe, been obtained in the Museum of the College of Physicians for this collection. Dr. J. V. Ingham, Secretary of the Society, will receive specimens, and will furnish any further information required.

Telegraphic Connections.—Arrangements have been made by which the Fire Alarm and Police Telegraph of Philadelphia is connected with the Pennsylvania Hospital and with the Episcopal Hospital by direct wires,—so that on the occurrence of accidents the authorities of those institutions may be at once notified. There will also be less delay than heretofore in summoning members of the visiting staffs when their services are needed.

We find the following in a daily paper: "A valuable present of Peruvian skulls has lately been received by the British Anthropological Institute from Consul Hutchinson, of Callao. This highly instructive series consists of one hundred and fifty specimens dug out—not gathered from the surface—of the old aboriginal burying-grounds of Pasamayo and of Ancon, twenty and thirty miles north, and from Corso del Oro, about one hundred miles south, of Callao. Twenty-four of these were taken by the consul himself from the Huancas of Ancon, and are probably those of Chinchas or perhaps Ayonaras."

The problem of the maintenance of Continental population is editorially discussed in the *Medical Times and Gazette* (February 8), under the heading "Infant Deficit Abroad." The writer attributes much of the infant mortality to the wide-spread repugnance of mothers to nursing their children, out of which grow those evils of baby-farming and premature weaning which make this "the era of nursing-bottles and artificial food," and remarks that a flippant observer would be justified in "suggesting that formerly children had their milk on draught, but now they have it in bottle."

Medical Remuneration.—The Scotch have a proverb that

> "You should take the fee
> When the tear's in the e'e."

It would be well for us if we could always act on this distich. With many persons the benefits which they receive from their medical attendants are forgotten as soon as rendered. The doctor is a very different person in the eye of his patient when he comes to relieve pain and suffering and when his bill is presented for payment after an interval of months, or it may be in some instances years.

The *Druggists' Circular* for February says, "A physician should always date all his prescriptions. The date should be written first. He is a careless man who omits it, and one to whom we should not care to intrust our life. If the druggist chooses to stamp the prescription, when he has dispensed it, with his name and the date, there can be no objection. On the contrary, it is better that he do so."

European and East Indian women are now, according to the *British Medical Journal*, receiving regular instruction in midwifery and nursing. At the Madras Medical College, diplomas are granted after the required course of study and the passing of satisfactory examination by the candidates.

On January 2, a new European hospital was opened in Kioto, Japan, under the direction of Dr. Junker, who for some time was physician to the Samaritan Hospital, and who directed the English Red Cross Society Hospital at Saarbrück during the Franco-German war.

The largest number of deaths from scarlet fever in England from 1866 to 1870 was in 1870, when 32,543 died.

Population of Germany.—Including Alsace and Lorraine, the subjects of the Kaiser number, according to the census of December, 1871, 41,058,000. The females are in excess of the males by 768,000.

A census of the horses liable to be taken for military service is soon to be taken in France. The work is to be placed in the hands of a mixed commission of civilians and army officers.

Herr Ritter von Mauthner has devoted the sum of 260,000 florins to the establishment of a hospital for children in Vienna.

Dr. J. C. Nott, of Mobile, died in that city on the 31st ult., on his sixty-ninth birthday.

Mortality of Philadelphia.—The interments reported at the Health Office for the week ending March 29, 1873, were 323; 172 adults, and 151 minors. 8 were of bodies brought from the country; making the mortality of the city 315. Among the assigned causes of death were:

Consumption of the Lungs	52
Other Diseases of the Respiratory Organs	55
Diseases of the Circulatory Apparatus	19
Diseases of the Brain and Nervous System	44
Diseases of the Digestive Apparatus	19
Zymotic Diseases (Scarlet Fever 6, Smallpox 3)	23
Typhoid Fever	7
Diseases of the Urinary Organs	15
Casualties	13
Cancer	5
Rupture of Uterus	1
Debility (including "Inanition" and "Marasmus")	30
Still-born	13
Old Age	9

(The interments reported for the week ending March 30, 1872, were 449.)

The meteorological record kept at the Pennsylvania Hospital was as follows:

	Thermometer. Max.	Min.	Barometer. (2 P.M.)
Mar. 23	55.0°	31.0°	29.93 in.
" 24	36.5	35.5	30.22 in. (Rain and Sleet.)
" 25	35.0	30.0	30.14 in. " " "
" 26	40.0	33.5	29.62 in. " " "
" 27	38.0	27.0	30.28 in.
" 28	51.0	32.0	30.35 in.
" 29	54.5	49.0	29.37 in. (Rain.)

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 25, 1873, TO MARCH 31, 1873, INCLUSIVE.

Styer, Charles, Assistant-Surgeon.—Leave of absence extended to include May 10, 1873. S. O. 66, A. G. O., March 28, 1873.

Ewen, C., Assistant-Surgeon.—Assigned to duty at Little Rock, Ark. S. O. 47, Department of the Gulf, March 24, 1873.

Winne, Charles K., Assistant-Surgeon.—Leave of absence granted for six months from April 15, 1873, and his resignation accepted by the President, to take effect October 15, 1873. S. O. 55, A. G. O., March 15, 1873.

SATURDAY, APRIL 12, 1873.

ORIGINAL LECTURES.

LECTURES
ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. Bertolet, M.D.

(Continued from page 419.)

Lecture VII.

INJURIES TO THE LARYNX AND TRACHEA.

Burns and Scalds.—Burns and scalds of the larynx and adjacent structures of the throat are met with, usually as the result of accident, but sometimes as the effect of design. They are often fatal. Acids or alkaline caustic fluids are sometimes swallowed, a liniment being mistaken for a mixture, or a glass containing acid for a drink of spirits. Children frequently suffer with scalds from attempting to drink boiling water. Another frequent cause is the swallowing of caustic substances with suicidal intent. The inhalation of flame, hot steam, or heated air, will produce burns in the air-passages. The larynx is less likely to be implicated when the caustic liquid has been swallowed involuntarily than when the drink has been taken designedly, and the epiglottis not surprised at its post, as it were; the effects are produced chiefly in the pharynx and œsophagus, and sometimes the stomach, the act of deglutition being fully accomplished in spite of the pain and spasm. Boiling water, not being taken designedly, is rarely if ever swallowed, spasmodic regurgitation taking place before the act of deglutition is completed.

There is usually very little trouble about the diagnosis of a burn or scald of the larynx, except in instances where the nature of the accident is concealed by the determined suicide. The severe pain and distress in the parts, the great acceleration of the pulse, and other evidences of vascular excitement, the dysphagia, the dyspnœa with its usually attendant stridulous inspiration, the pallor of the countenance, the coldness of the extremities, the nervous excitement, and the history of the case, are sufficient for the purpose.

If the case is seen early, and the parts can be subjected to inspection, there is generally noticed a tumefaction and destruction of the mucous and sub-mucous tissues of the palate, the pharynx, and larynx, which are of a white color, often from detachment of the epithelial layer, in a membranous form, or from prompt plastic exudation. Acute laryngitis supervenes rapidly, and is likely to be attended with œdema, and its risk of death by asphyxia. In addition to this, there is usually a great amount of nervous shock, which in itself constitutes a serious element of danger.

As a rule, only the upper portion of the larynx becomes implicated,—that is, the region above the glottis,—all the lower portions of the larynx having often been found normal after death. In other instances, however, the mucous membrane of the trachea and bronchi has been found congested and swollen, with sometimes, also, inflammation of the lungs. In some instances a plastic exudation, resembling in its character the plastic exudation of croup, has been found in the trachea and in the bronchi.

The local treatment of acute laryngitis from burns and scalds consists in applying cold compresses or ice-bags about the neck, and keeping bits of ice in the mouth. The inhalation of the spray of acetate of lead, or its frequent projection on the parts, would seem applicable, in view of its beneficial effects in scalds and burns of the cutaneous surface. The use of mucilaginous drinks, where practicable, is very soothing. The external application of leeches about the throat, and, in some cases, of blisters following, has also proved efficacious.

The operation of tracheotomy or of laryngotomy is usually indicated, however, and should not be postponed too long. Inasmuch as the inflammation of the larynx rarely extends below the vocal cords, owing to the spasmodic closure of the glottis at the moment of injury, there is no objection, as a rule, to performing laryngotomy through the crico-thyroid membrane, especially in the adult whose parts will admit the insertion of a tube large enough for respiratory purposes. The operation, though by no means certain to save life in adults, offers more hope of success than it does in children.

Burns and scalds of the air-passages may result in stenosis of the larynx or trachea, which is usually attended with a persistent chronic laryngitis.

WOUNDS OF THE LARYNX AND TRACHEA.

Wounds of the larynx and trachea—gunshot, contused, and incised—are encountered in both military and civil practice. They are accidental or designed; most frequently occur in suicides, but sometimes are inflicted by murderers. Brierre de Boismont found that of four thousand five hundred and ninety-five suicides, one hundred and twenty-one had cut their throats. Suicidal attempts of this nature fail in producing death more frequently than they succeed; partly from ignorance of the locality of the great vessels, and partly from belief that a wound of the windpipe is necessarily fatal. The head being usually thrown backward, the large vessels are pressed out of the reach of the knife, and the air-passage alone wounded. Malgaigne states that the larynx is found severed in young suicides only,—old ones wounding the trachea more frequently; and he puts the query whether this is not due to the circumstance that an old person cannot throw his head so far back as a young one. When the suicide understands the anatomy of the parts, or makes a sweeping cut, the great vessels of the neck are severed, and death from hemorrhage follows quickly.

Incised wounds above the hyoid bone, though

they open into the mouth and pharynx, and sometimes wound the root of the tongue to such an extent as to produce serious hemorrhage, do not implicate the larynx.

If the wound is made below the hyoid bone, then the pharynx is entered, and the upper portion of the cavity of the larynx opened or exposed; the epiglottis being sometimes wounded, and even the arytænoid cartilages severed. In some instances the hyoid bone and the tongue are severed from the larynx. When the epiglottis or an arytænoid cartilage has been partially severed, there is risk of impaction of the fragment in the glottis, an occurrence which may take place soon after the injury, or not until some hours or days afterwards. Cases are on record of fatal results from both of these complications. It is, therefore, very generally deemed advisable to remove with the knife or scissors any movable fragment of epiglottis, arytænoid cartilage, or other structure, the retention of which might give rise to such an accident.

When the knife has been applied several times to the throat, the cartilages are sometimes divided into several fragments, and great care must be taken that no loose piece of cartilage be allowed to remain, lest it become detached and obstruct the glottis. In cases of multiple wounds of this kind the immediate danger from entrance of blood into the air-passages is much greater than where there has been but a single cut. This danger from hemorrhage, too, is much greater in wounds of the trachea than in wounds of the larynx, because the thyroid gland is almost always wounded also.

The diagnosis of a wound of the larynx or trachea is sufficiently simple, even before thorough exploration of the nature of the injury, by the passage of air through the wound, and the presence of frothy blood at its surface. If the patient is not suffocated by the blood which has flowed into the air-passages, it is expectorated through the wound, and partly through the mouth. Syncope is a usual result of the hemorrhage. Liston, Rush, and others caution the practitioner against being deceived by the arrest of hemorrhage on the occurrence of syncope; for, if ignorant, he will close the wound by suture, and prevent the outward escape of blood in the subsequent hemorrhage which is almost sure to occur as soon as reaction is established; and then the patient may be drowned by his own blood, or be asphyxiated by the formation of a clot. Cases made fatal in this way by too assiduous attention are on record; and Liston mentions an instance in which his own assistant, despite the principles that he had inculcated over and over again, came near losing a patient in this way, whom Liston saved by cutting the sutures and removing the clot which impeded respiration.

It is, therefore, an important point in the management of cut-throat cases, that the parts should not be united by suture until it is certain that all danger from hemorrhage is over. Ligation of the bleeding vessels does not always secure immunity from later and recurrent hemorrhage. If the hemorrhage is excessive, and unrestrainable by styptics and the ligation of vessels within reach, perhaps the best treatment would consist in tying the carotid, a measure which has frequently been carried out with satisfactory results. If the wound be large, it is allowable to unite its outer portions, leaving the central portion open; and if there is any disposition towards bagging of a horizontal wound, the pockets at its lower lip should be divided vertically, so as to prevent the burrowing of pus; for these wounds never unite by first intention, and more or less extensive suppuration is to be expected. When all danger of hemorrhage is over, the parts on either side of the opening in the air-tube can be brought together with adhesive strips and sutures, if necessary,—ample room being left for drainage; but no suture should be taken through the cartilage, or even its perichondrium, inasmuch as sutures are not well borne in these situations, and either cut themselves out or produce so much local irritation as to necessitate their removal. After the parts are in apposition, the head is to be slightly flexed, and retained in its position by light bandaging. The parts should be covered with light gauze or something of the sort, to modify the temperature of the inspired air. The patient's apartment should be warm, and the air moist.

Inflammatory reaction is to be treated on general principles. If from any cause asphyxia be threatened, the trachea should be opened below the seat of injury, and a canula introduced.

If there is no wound of the pharynx or œsophagus, food can usually be taken by the mouth, even if the epiglottis has been wounded; if these structures have been injured, liquid nourishment can be given by a stomach-tube; and, under extreme circumstances, by the rectum. Medicine, if required, can be given by enema or by hypodermic injection. Care must be taken to catch the expelled secretions in a soft sponge or mop, and to cleanse the wound frequently. Despite the utmost attention, however, more or less bronchitis will ensue, attended with copious secretion. Opium may be employed to restrain the secretion and allay cough; but care must be taken not to push it far enough to obtund the sensibility of the larynx and trachea, and thus favor the passage of fluids into the larynx. These wounds heal slowly. They often leave a fistulous passage, requiring the use of caustics, or even calling for plastic operations. Sometimes stenosis ensues, necessitating the permanent use of a tracheotomy-tube.

Gunshot wounds of the larynx and trachea occur in the same localities as incised wounds. The primary hemorrhage is less, but the secondary hemorrhage may be profuse, especially in wounds of the trachea, on account of injury to the thyroid gland. The main source of danger is from the inflammatory swelling of the superjacent soft parts. The resulting bronchitis is apt to be very severe, with profuse muco-purulent secretion.

Severe gunshot wounds are liable to be complicated with contusion or laceration of important nerves, and there may be paralysis or spasm of the intrinsic laryngeal muscles, interfering with respiration, independently of œdema or inflammatory

products; and this condition of things may demand tracheotomy, in order to render respiration independent of the patency of the larynx.

FRACTURES OF THE LARYNX AND TRACHEA.

Fractures are the result of mechanical injury. They are simple or multiple. The thyroid and cricoid cartilages are fractured most frequently. The prognosis is always grave, especially when the cricoid cartilage is implicated; possibly because the injury which breaks this strong circular cartilage produces great contusion of the soft parts.

The symptoms of fracture of the larynx are, essentially, spasmodic cough, frothy sanguinolent expectoration, dyspnœa, dysphonia or aphonia, dysphagia, and emphysema in some cases attended with laceration of the mucous membrane. Cartilaginous crepitation is produced on manipulation. It must be borne in mind that the upper horn of the thyroid cartilage is occasionally found disconnected from the body of the cartilage; and sometimes, as in a specimen exhibited by the lecturer, it is entirely absent.

Some fractures terminate fatally at once or in a short time. If the patient survive the immediate injury, tracheotomy ought to be performed to lessen the risk of danger from sudden asphyxia. In many instances the emergency calling for this operation has presented suddenly, and the patient has been lost because there was no one present to perform it. The fragments should be carefully replaced, but no sutures should be taken in them, for the same reasons given in treating of wounds of this region. In fact, the general after-treatment would be very much like that adopted for wounds.

The symptoms of fracture of the trachea are similar, in the main, to those of fracture of the larynx: severe dyspnœa and rapidly extending emphysema. The prognosis is very unfavorable. The treatment is much the same as for fracture of the larynx, including the prompt laying open of the wound, and the insertion of a tracheotomy-tube, or the performance of tracheotomy below the seat of injury.

Rupture of the trachea from the larynx, or of one or more intercartilaginous spaces, occasionally happens under severe mechanical injury, such as pressure, or a kick on the parts. Spontaneous laceration has also been known to occur. The main diagnostic symptoms are dyspnœa and emphysema. Tracheotomy is usually called for. The cases usually terminate fatally.

Contusions of the larynx and trachea sometimes occur as the result of accident or violence. They are usually amenable to rest and emollient applications. Spasm of the glottis may ensue and necessitate the operation of tracheotomy.

FOREIGN BODIES IN THE LARYNX AND TRACHEA.

Foreign bodies almost always gain access to the larynx and trachea from the outside, but sometimes from the inside also. Thus, a detached bronchial gland, a piece of necrosed laryngeal or tracheal cartilage, may become a foreign body to all intents and purposes. Parasitic worms, insects, etc., sometimes crawl into the air-passages; and sometimes matters from the stomach may be vomited into the larynx. The foreign body remains loose, or may lodge in some portion of the passage. The symptoms of the presence of a foreign body in the air-tube are: cough, pain, spasm, and dyspnœa; and the diagnosis is usually dependent upon the suddenness of the onset. Auscultation of the larynx, trachea, or lungs, sometimes affords the evidences of obstruction; and occasionally the foreign body, especially when lodged, can be seen in the laryngoscopic image. Impaction of a foreign body in the pharynx or œsophagus may give rise to all the subjective symptoms of a foreign body in the larynx or trachea. Exploration with the finger and with the stomach-tube will soon set this point at rest.

Spontaneous expulsion of a foreign body often takes place, but it is hardly safe practice to trust to this result, in view of the accidents which may occur if it is retained in the air-passages, on the one hand, or caught in the glottis, on the other.

If the substance inhaled has been a soft vegetable material capable of absorbing moisture, its prompt removal should be effected. In fact, it is hardly doubtful that prompt removal is the best practice in all cases of this kind; for the life of an individual with a foreign body in the air-passages cannot be said to be safe. If the foreign body can be seen with the laryngoscope, it may, in favorable instances, be removed with the laryngeal forceps, or hook; but only, as a rule, when situated above the glottis.

Under most circumstances, an opening should be made in the trachea, large enough to admit of the free play of instruments for extraction. The opening should be at least an inch and a quarter in length in the adult, and an inch in the child. If the foreign body is in the larynx, laryngotomy may do; but sometimes it is necessary to divide the wings of the thyroid cartilage to a certain extent. Sometimes the foreign body is expelled by cough as soon as the air-passage is opened, and it may escape either by the mouth or by the wound. Sometimes the foreign body presents at the wound and is seized in the forceps. If it does not make its appearance at the point of incision, it is customary to slap the patient on the chest and back while the face is turned downwards, and thus to dislodge the body and favor its expulsion.

If these efforts fail, delicate forceps or blunt hooks are carefully passed into the tube to search for the body and draw it out. They should always be warmed before they are introduced. Care must be taken not to impact the body in the manipulation. These efforts must not be continued many minutes. If they fail, the wound is to be kept open by ligatures in its edges, fastened together at the back of the neck, or by hooks or wires similarly secured. The parts are covered with a light compress, to exclude the entrance of cold air. Then renewed efforts at extraction are made in a few hours, or on the next day. The wound should be kept patulous until the

foreign body is expelled. If this does not take place soon, a tracheotomy-tube can be worn, and withdrawn when the body shows signs of dislodgment. For the first few days of keeping such a wound open, the patient should be confined in a warm room with some moisture in the atmosphere.

ORIGINAL COMMUNICATIONS.

STRABISMUS CONVERGENS:

WITH SPECIAL REFERENCE TO ITS ÆTIOLOGY.

A Paper read before the Northern Medical Association of Philadelphia.

BY S. D. RISLEY, M.D.

THE term "strabismus" was formerly applied to all deviations of the optic axis from parallelism. In later years, however, since the paralyses of the ocular muscles have been more carefully studied, and with a better understanding of the causes of squint, all deviations depending upon paralysis or muscular insufficiency from any cause, or mechanical obstructions to the movements of the eyeball, have been excluded, and the term limited to that group of cases *characterized invariably by the fixing of one eye upon the observed object, while the other deviates from its normal direction,—the degree of movement in both being equal and normal.*

Either of the muscles of the eyeball may be the immediate agent in causing the deviation; but the two by far most frequently demanding attention are the rectus internus and rectus externus, and these in point of frequency in the order of their naming. They pull the eye in opposite directions, and the abnormal deviations produced are termed *strabismus convergens*, or where, the internal rectus acting, the eye is carried towards the nose, the cornea being buried more or less deeply at the inner canthus, and *strabismus divergens*,—where, the external rectus acting, the eye is rolled outward, and the cornea buried at the outer canthus. Of these the first occurs more frequently; and it is to this variety of deviation I desire to invite your attention, and more particularly to *its cause* than to its diagnosis or treatment.

In well-marked cases of strabismus there can be no difficulty in recognizing the deformity. The only question which needs any share of our attention is the differentiation of true strabismus from other deviations of the optic axes. The more frequently occurring conditions liable to lead to error in diagnosis are the paralytic affections of the muscles of the orbit, orbital tumors, and certain optical defects giving rise to apparent strabismus. The principle upon which the differential diagnosis is to be made out is contained in the definition already given. In no other affection will the same conditions be met. In paralysis of the external rectus of one side we shall find convergence of the corresponding eye, while the opposite eye fixes the object, but there will not be the same degree of movement in each eye. In orbital tumors we may have convergence, but the movements of the ball will be impeded. Lastly, in cases of apparent convergent squint it will be found that not one but both eyes converge, and that though both eyeballs are deviated inward, nevertheless both eyes are fixed upon the same object. Again, this condition is associated with high degrees of myopia.

The question usually to be decided is between deviation from paralysis of one external rectus and true strabismus. To render the subject more intelligible, suppose a case of convergence of the right eye. The patient observes you steadily with his left. If an opaque card or the hand be placed before the left or fixing eye, the right or deviated eye will move outward, if the case be one of strabismus, in order to fix upon any object at which he may be directed to look, placed directly in front of him, and the left eye will be found to have made an associated movement inward, as the before converging eye moved outward to fix upon the observed object, and to have now become the squinting eye. If the extent of the *primary* deviation be measured, and afterwards the associated movement of the healthy eye, or *secondary* deviation as it is called, they will be found equal. On the other hand, if the case be one of paralysis of the external rectus of the right eye, when the healthy eye is covered the left will make an irregular oscillatory or zigzag movement, brought about by the action of the oblique muscles in the vain attempt to move the eye outward. If the case be one of *partial* paralysis, it will probably move outward to some extent—a line or a line and a half—in the attempt to fix its visual axis upon the object. The sound eye, however, it will be found, has made an associated movement inward of $2\frac{1}{2}'''$ to $3'''$. This greater *secondary* deviation is explained by Soelberg Wells in the following manner. "As the external rectus of the unsound eye is insufficiently innervated, it demands a greater impulse of the will to bring about this diminished movement than if the innervation were normal. But this increased impulse also affects the associated healthy internal rectus of the opposite eye, and is enabled to produce a greater amount of movement in the eye. Hence it is an invariable rule in all cases of paralysis that the secondary deviation considerably exceeds the primary, whereas in the common concomitant squint the two are exactly equal." There will also be a marked difference in the mobility of the eyes in following an object moved rapidly from one half to the other of the field of vision, and in slight cases valuable aid may be afforded by the diplopia consequent upon the want of concord in the optic axes: *e.g.*, when the object is moved over into that part of the field of vision corresponding to the partially paralyzed muscle, the eye, being no longer able to follow the object, becomes fixed at some point, while the other eye follows the object. In this way a convergent squint is produced, and homonomous double images are seen. For it will be seen that the rays of light from the object fall upon the inner portion of the retina, accustomed only to receive rays coming from the outer part of the field of vision: hence the image is from habit projected in that direction.

The operation for the relief of the deformity is

without doubt of comparatively modern origin. Empiricism, however, seems to have led the van of the army of more scientific and worthy investigators by nearly a century. About the middle of the last century a famous charlatan entered Paris, and in conspicuous announcements proclaimed himself oculist to the King of Great Britain, and claimed to have discovered "a mode of restoring squint eyes by a prompt operation, almost without pain, and without the fear of any accident." (Giraldés, by Velpeau.) He passed by means of a needle a silken thread under a fold of the conjunctiva, and with the scissors divided the included tissues. The sound eye was then covered with a plaster, the squinting eye was restored, and by the clamorous crowd it was pronounced "a miracle." (Secat.) He is said to have given as a reason for the operation that "strabismus is caused by an inequality of the muscles of the eye, and in order to cure it one of them must be weakened." After this the operation seems to have been forgotten, until our own Gibson suggested it in this country, and performed the operation in four cases in 1818. But he was subsequently induced, through the influence of Professor Physick, to abandon it. (Smith.) European writers, however, justly claim for Stromeyer the credit of having in 1838 brought the operation into general notice. He himself claimed the operation as something entirely new. At the time of his minute description of his operation he had only performed it on the cadaver. To Dieffenbach belongs the honor of establishing the success of the operation, publishing his first essay in 1839. After these came Phillips, Baumgarten, Velpeau, Guerin, Guthrie, Liston, Elliot, Hall, and others of the continental and British surgeons; and it was done in the United States by Willard Parker, of New York, in 1840, and soon after by Pancoast, and others of this city. The literature of the subject furnishes a sad record, not only for the patients who sought relief at the hands of these eminent surgeons, —for their efforts were far from being uniformly successful,—but also because of the grossly exaggerated accounts of success contained in the published reports of the continental surgeons during the first years after the inauguration of the operation for squint. Others, led by these reports to too sanguine hopes, were not sparing in their denunciations of those who had led them astray. A strong partisan feeling crept into their writings. The crimination on one part, followed by epithets of "ignorance," "incompetency," "tyro," etc., on the other, manifested a spirit strongly at variance with the genius of the profession, and one which always forms a barrier to the progress of truth. I would that thirty years later we were entirely free from the same spirit! But how often the enthusiastic reports of brother practitioners prove but the uncertain light of the *ignis fatuus*, luring others on to naught but disappointed hopes and the criminations of their patients! Truth can never be established save upon the foundation of honest observation. Exaggerated reports of success can only, sooner or later, lead to disclosure and just denunciation; while the truth, even though it be a report of negative results, is a valuable contribution to our science.

In works on general surgery written within the last decade, we find repeated asseverations of personal success, and unmerited censure visited upon less fortunate or perhaps more honest rivals in the operation for strabismus. How little consideration is due these claims to unvarying success the sequel will show. The statements are exaggerated, or the cases have not been watched sufficiently long after the operation. Velpeau, as early as 1840, in estimating the proportion of failures to cures, etc., seems to have grasped the real state of affairs leading to exaggerated reports of success, and to guard against it lays down two important considerations:—1, the careful determination of the nature of the case operated upon; 2, to exhibit the patient cured after three months. He had repeatedly seen cases of vaunted cures return after a short interval with the eye turned outward, after having before squinted inwardly, or who still continued to squint as before. Alluding to these experiences, he says, "These things at Paris have brought odium upon the operation, so that its intrinsic value, after unexampled popularity, begins to be mistrusted."

Ignorant as they were of the ultimate cause of the deviation of the optic axes in a vast majority of cases, it is not surprising that surgeons should have looked to the ocular muscles for the relief of a deformity in the production of which they were obviously the immediate mechanical agents. Stung by their want of success, and by the frequent recurrence of the deviation, they were led to perform extensive dissections of the ocular muscles and their cellular investment. Thinking the return of the squint due to the action of the oblique muscles, or the internal fibres of the superior and inferior recti, *these* were divided, and many times with extensive denudations of the eyeball, but with no better results, —the deformity returning quite as frequently, often the eye squinting in the opposite direction, and the deformity magnified by the extensive denudations. After such wholesale laceration of the muscular attachments, the eye was permitted, in many cases, to bulge forward: hence we find to-day, in many of the books, this condition given as one of the results of the operation for the cure of strabismus. It is not the case, however, after a judiciously performed tenotomy.

Owing to this liability to recurrence, and the imperfect results attained even in the so-called successful cases, many surgeons gave no encouragement to patients applying for relief.

Such was the uncertain estimate placed upon the value of the operation for the cure of strabismus, when in 1858 Professor Donders, of Holland, during his investigations upon asthenopia, discovered its cause in the hypermetropic structure of the eye. Henceforth strabismus was to lose its importance as a distinct affection, and to be regarded as a symptom merely of an ulterior condition.

In the normal eye, rays of light emanating from distant objects—*i.e.*, parallel rays—are, without effort of the accommodation, brought to a focus upon the retina by the refracting system of the eye,

and a clearly-defined inverted image of the object is thrown upon the layer of rods and cones of the retina,—a condition necessary for distinct vision. Regarding the eye as an optical instrument, it resolves itself into a refracting apparatus, the cornea and lens, and a receptive screen, the retina.

It is obvious that, in order to have perfectly-defined images, there must be harmony between the refracting power and the distance at which the screen, or retina, is placed.

Thus, if the eye be regarded as a camera of one inch in length, it must have a refracting power which would be equal to a lens of one inch focal distance, in order that images of distant objects be accurately pictured upon the rods and cones of the retina; or, having a refracting power equal to a lens of one inch focal distance, it is obvious that any variation in the position of the retina, without a change in the refracting apparatus, would lead to imperfectly-defined images upon the retina, and thus to indistinct vision.

It has been demonstrated that there are frequent departures from this harmony, so necessary to perfect vision and comfortable use of the eyes.

Eyes which enjoy this harmony are termed emmetropic. There are two other conditions, however, which have been repeatedly demonstrated,—the one in which the visual axis is too short, the other in which it is abnormally long. In the first, the converging cone of rays is intercepted before reaching the principal focus, and in consequence a circle of diffusion results, instead of the perfectly-defined image. In the second, the rays of light, having reached the focal point, cross over and reach the retina as diverging rays, again giving a circle of diffusion.

The term hypermetropia has been given to the first; the second is the anatomical condition in myopia.

It is the hypermetropic eye with which we have most to do in this paper.

These conditions may be illustrated optically by a schematic eye, consisting of two cylinders, the one moving freely within the other. At the anterior extremity of the outer cylinder is placed a plano-convex lens, with a focal distance equal to the length of the cylinder. Over the posterior end of the contained cylinder is placed a ground-glass screen, upon which is delineated an inverted but accurate image of the distant burning jet of gas. As the relative position of the screen is changed by moving the inner cylinder, either within or without the principal focus of the lens, we get no longer the perfect image, but a circle of diffused light.

Now, what we see here demonstrated in this schematic eye also takes place in the human eye in hypermetropia and myopia. When the ground-glass screen is moved within the principal focus of the lens, the condition is optically hypermetropic. In order to again secure an accurate image, the refractive power and the distance of the screen must be made to harmonize, which may be done by placing an additional lens in front. In the hypermetropic eye, nature has furnished this additional lens through the power of accommodation, by virtue of which the lens becomes more convex, its refracting power being thereby increased.

It is not my purpose in this paper to explain the mechanism of accommodation any further than the mention of the fact that this power of accommodation is resident in the ciliary muscle within the eyeball. The contraction of the fibres of the muscle relaxes the suspensory ligament, and allows the elastic lens to expand, its convexity thus becoming greater, and its refractive power increased.

It follows, from what has been said, that hypermetropic eyes are able, without tension of the accommodation, only to focus rays which enter it more or less convergently. Theoretically, light is reflected from bodies to the eye in a diverging direction; but so long as the rays diverge at any angle no greater than 5′, they are practically parallel, and in investigations upon the dioptrics of the eye are so considered. Rays of light emanating from infinitely distant objects are regarded as parallel, and in the emmetropic eye such rays are without tension of the accommodation focussed upon the retina. With the hypermetropic, however, it is different. As we have seen, the principal focus of the refracting system of his eye is behind the retina, and the refractive power must, therefore, be increased in order to focus parallel rays upon the rods and cones. Now, the amount of accommodation required to accomplish this may be regarded as a deficit with which the hypermetropic individual commences life. With the approximation of objects to the eye, for the maintenance of binocular vision, the axes must converge more and more. At the same time, the rays of light from the object enter the eye more and more divergently, calling for an increase in the accommodation in a direct ratio to the approximation of the object.

Now, together with the increase in the convergence, there is also an increase in the power of accommodation. That this is true may be demonstrated in various ways. If a prism be placed before the eye of a hypermetropic individual (*e.g.*, one who is unable to focus parallel rays with V = $\frac{3}{4}$ for distance (Sn. $\frac{15}{XX}$)), with its base outward, in order to avoid diplopia he squints inward, and the acuity of vision comes up to 1, or Sn. $\frac{15}{XV}$. With the excessive convergence thus induced, he can bring his faculty of accommodation more powerfully into action, and is able thereby to focus parallel rays upon his retina.

When we wish to put our power of accommodation upon the stretch, there is a strong tendency to increased convergence, even in emmetropic eyes; but it is pre-eminently so with hypermetropic individuals who are compelled to employ continually more or less tension of the accommodation. An emmetropic person may readily convince himself of this by producing an artificial hypermetropia by means of negative glasses placed before the eye, sufficiently strong to quite neutralize the power of accommodation. With every effort at distinct vision through them, double images confuse him, and he must either be content with indistinct vision, or permit a convergent squint. This will be rendered more

apparent by placing a prism with its base outward before one of the glasses. Momentarily double images will appear, to avoid which the eye squints inwards, and distinct vision is attained as by magic.

The same thing often occurs in hypermetropia, the one eye squinting inwards in order to increase the power of accommodation.

It is in the fact, then, *that "the more strongly we converge, the more powerfully can we bring our faculty of accommodation into action," that we find the tendency to abnormal convergence in hypermetropic persons, and in hypermetropia that we find the secret of strabismus convergens.*

That these theoretical considerations do not lead us astray we are assured by a number of circumstances. In the first place, it is rare to find a case of strabismus convergens which is not associated with hypermetropia. In fact, so nearly constant is this, that the oculist at once sets about the determination of the degree of hypermetropia when consulted by persons for the deformity of squint eyes, with very much the feeling that *so many cases of strabismus convergens, so many cases of hypermetropia.*

I have seen but one case of pure strabismus not depending upon opacities which was not associated with hypermetropia. This case consulted me for convergent alternating squint. His acuity of vision, as determined by Snellen test-types, was normal, and in each eye I could detect no manifest hypermetropia, either by trial with glasses or by means of the ophthalmoscope. There was no visible cause for the deviation,—*e.g.*, opacities in the media,—and the fundus appeared healthy. There was no want of power in any of the ocular muscles.

I proposed tenotomy, but suggested to him the possibility of his being obliged to wear spectacles in the future, to prevent the return of the deformity, *so certain* was I, from past experience, that hypermetropia was the hidden cause of the deviation. After thorough paralysis of the accommodation, to my surprise I was unable to detect the slightest degree of hypermetropia. The parallelism of the axes was restored by the operation, but there was no need for spectacles. I relate this case as an exception, and for the sake of the contrast it affords. Donders found that hypermetropia existed in seventy-seven per cent. of the cases, and, in concluding his remarks, states that cases of deviation were included "which it is not usual to refer to the head of strabismus convergens, as tolerably recent cases of paralysis of the abducent muscle, too strongly convergent, nearly immovable myopic eyes, etc. I therefore," he says, "do not hesitate to declare that it is exceptional to find strabismus convergens without hypermetropia."

(To be continued.)

UTERO-PLACENTAL VACUUM.

BY H. G. LANDIS, M.D.,
Niles, O.

WHOEVER has seen a boy's leather "sucker" will readily notice on reflection that it is of very similar mechanical construction to the placenta. As we used to make the aforesaid instrument, it was a circular piece of leather with a string centrally attached. When made pliable by moisture, and applied firmly to a brick, traction on the string resulted in a vacuum beneath the leather, which was so forcibly held down to the brick that the latter could readily be raised from the ground by it. For the sure performance of this feat a flat surface on the object to be lifted was an essential; and this requisite being absent in the womb is the probable cause of the rarity of the accident which is exemplified below, and which seems to deserve the name prefixed to these remarks; for the placenta has every other requirement for its occurrence.

February 9.—Was called to Mrs. M., one hour and a quarter after childbirth. Her labor had been short, but the midwife in attendance could not deliver the after-birth, although she had spared no effort. I found the placenta partially protruding from the womb by a hard conical eminence a little to one side of the attachment of the cord. Seizing the cord, I made as much traction as it would bear, aiding this by external pressure on the uterus, squeezing the womb, etc., all of which had no effect. The idea of a vacuum then coming to my succor, I perforated the placenta, and on withdrawing the hand from the vagina it was at once and rapidly expelled as far as the perineum without any traction at all. No clots followed, and the placenta was of medium size.

Cazeaux mentions almost every possible cause of detention, but not this. Although I have never noticed it unmistakably before, I am inclined to think that some of the cases generally ascribed to the apparent great bulk of the placenta due to the formation of clots, are rather of this nature. In the case just mentioned, the predisposing cause appears to have been a capacious vagina which readily admitted the external air. The immediate cause was traction at an improper time, not before the placenta was detached, for it evidently had been, but before its edge could be felt at the os uteri, after which this or indeed any other of the difficulties in delivering the after-birth are unlikely to occur.

March 15, 1873.

TRANSLATIONS.

A REVIEW OF DOLBEAU ON PERINEAL LITHOTRITY.*

BY S. DUPLAY.

(Translated from the *Archives Générales de Médecine*, Paris, January, 1873.)

"WHEN we long study any subject, we end by becoming penetrated with it, and succeed in forming for ourselves an entirely personal opinion. The ideas which result from such an experience are the product of reflection, and we may believe they are properly our own. Yet these same ideas may be found either in germ, or fully expressed by those who have preceded us in writing upon the same subject."

Thus M. Dolbeau expresses himself in the introduction of his book; and doubtless some little surprise will be felt, after having seen these judicious remarks, which appear to exclude the idea of a new invention, when we

* "On Perineal Lithotrity, or a New Mode of Operating upon Calculous Patients." Paris, 1872.

note that the author retains for his book the double title of "Perineal Lithotrity, or a *New Mode of Operating upon Calculous Patients*." I should fear to enter anew upon a discussion which seems to me exhausted, and which has been the subject of an extensive article in this journal,* endeavoring to establish that perineal lithotrity is not, properly speaking, a new operation, either as conceived or as executed. But if I refuse to admit that the operation may really be a new mode of operating upon calculous patients, and if consequently I criticise this sub-title of the work of M. Dolbeau, I have not the least intention of detracting from the merit of the author, who, in reviving an old idea, in perfecting the mode of the operation and the instruments, has made perineal lithotrity an established operation, and one which seems to me to be destined to effect a material advance in the treatment of vesical calculi.

Although the operation of perineal lithotrity has been described several times by M. Dolbeau, either in his "Treatise on Stone" or before the Society of Surgery, it was indispensable, in order to popularize the method and to furnish the proper data to judge of its value, to present in all its details the manual of the operative procedure, the natural sequelæ of the operation, its accidents and complications, and finally the results which have been accomplished by it up to this time. Such has been the object of M. Dolbeau in publishing the memoir of which we give here a short analysis.

Before describing the operation of perineal lithotrity, the author devotes several pages to two points of anatomy and physiology intimately connected with the execution of the operation. These two points are: first, the exact situation of the bulb of the urethra in relation to the perineum, the anus, and the rectum; second, the dilatability of the neck of the bladder.

In relation to the first point, M. Dolbeau concludes from his numerous investigations that lesion of the bulb is extremely difficult to avoid in the various incisions designed to approach the bladder in the median line. The incision which he adopts to certainly avoid the bulb is [in the median line] only two centimetres at most, and terminates at the junction of the skin and mucous membrane at the margin of the anus. This incision, which would be absolutely insufficient to open the bladder, serves only to approach easily and puncture the membranous portion of the urethra in the first step of perineal lithotrity.

The dilatability of the neck of the bladder has been on the part of the author the object of interesting researches, especially in relation to the operation he advocates. The dilator which he employs, and which is really an excellent instrument, combines the following three qualities:

1. It distributes the dilatation over a great number of points at the same time.
2. It produces a cylindrical dilatation.
3. Finally, it permits the practice of dilatation with slowness, care, and uniformity.

In using this instrument, M. Dolbeau has convinced himself that the neck of the bladder can be dilated to two centimetres, and that beyond this limit the dilatation is accompanied with ruptures which vary with the volume of the instrument. This opening of two centimetres, although insufficient to admit of the passage of a large calculus, permits the introduction of powerful lithoclasts.

I cannot follow the author in the detailed description of perineal lithotrity. This embraces three principal stages:

1. The opening of the bladder.
2. The breaking up of the stone, or lithoclasty.
3. Extraction of fragments and of the calculous débris.

It is necessary to add the preparation for the operation, and the subsequent care of the case.

This subject is treated with the greatest care, and the author has not omitted any of the details of the operation, describing the difficulties which may be encountered, and the dangers which it is necessary to know how to avoid. Indispensable directions will be found for those who would practise this operation with safety, in relation to the instruments, the part of the assistants, the position of the patient, and, lastly, as to the execution of the different steps, the understanding of which, moreover, is facilitated by the introduction of numerous figures in the text.

One of the most remarkable peculiarities of perineal lithotrity, when it is properly practised, is the simplicity and the benignancy of the sequelæ of the operation.

The singular fact that none of the patients have had incontinence of urine, I have verified myself. Desire to urinate is more or less frequent, and the urine then runs off by the perineal wound. By the second or the third day a part of the urine passes by the penis, and within an average period of two or three weeks the recovery is complete.

The immediate complications of the operation are few in number, and not serious in character, as pain, vesical tenesmus, and retention of urine. As to consecutive accidents, M. Dolbeau mentions ecchymosis of the scrotum and perineum, inflammation of the perineal opening, not unfrequently attended by incontinence of urine [? see preceding paragraph.—ED. *P. M. T.*], and, lastly, purulent infection, which was observed in two of his patients.

After an exposé so complete of the manual of the operation, and of the sequelæ of this operation, we should wish to find in the work of M. Dolbeau a critical statement of the indications for and against the operation. The author has endeavored to do this in a chapter on the comparative value of perineal lithotrity; but, if it seems to me decided that "perineal lithotrity" is superior to the several cutting operations, its comparative value to lithotrity by the natural passages has yet to be established, and this important point has, it seems to me, not been sufficiently elucidated.

The memoir of M. Dolbeau is terminated by the relation in detail of the operations which he has practised up to this time, and which number thirty cases, of which twenty-five were recoveries and five deaths.

(Signed) S. DUPLAY.

(We are enabled to add to those of M. Dolbeau three successful cases of this operation by J. W. S. Gouley, M.D., New York.† This gives a mortality in thirty-three cases of 15.15 per cent. In 544 cases of lithotrity performed in the usual manner there were 41 deaths,‡ or a mortality of 7.54 per cent.)

NOTES OF HOSPITAL PRACTICE.

CLINICAL NOTES.

WILLS OPHTHALMIC HOSPITAL.

SERVICE OF GEORGE C. HARLAN, M.D.

Reported by W. H. WINSLOW, M.D.

DETACHMENT OF THE RETINA.

M. W., a woman, æt. 27 years, in good general health, came to the clinic complaining of dimness of sight, which had come on suddenly some two months previously, before which her vision had been perfect; though she had always been myopic.

*Median Perineal Lithotrity, by Dr. Spillmann: *Archives Générales de Médecine*, 1869.

†See New York *Medical Record*, No. 4, vol. viii. p. 75.
‡See Ashhurst's Surgery, p. 845.

Externally, the eyes appeared healthy. Upon testing with Snellen's types, in the left V = $\frac{20}{L}$, in the right $\frac{20}{LX}$, and the field of vision in the latter was found contracted above the horizontal line and to the inner side; but she could count fingers below.

Ophthalmoscopic examination revealed, in the left eye, a large sclerectasia posterior, to the outer side of, and almost surrounding, the disk, with considerable engorgement of the retinal vessels.

In the right there was found a detachment of the retina below the horizontal line. She was ordered to wear blue coquille glasses and to give her eyes perfect rest; rather with a view of avoiding injury to the other eye, than with any expectation of improving the right; and to take elixir of quinine, iron, and strychnia, to improve her general condition.

Another case applied for relief, February 11, in the person of J. W., a robust man, æt. 28 years, a farmer by occupation, who was also myopic and had lost his left eye by a powder-explosion ten years previously, which slightly injured the right.

Vision in the right had always been good, until one warm day last summer, when he got overheated while at work in a corn-field and sat down to rest upon the fence.

Soon after he noticed a dimness of vision, which increased much when he jumped down, and he had to be led home. There had been no improvement since, and vision was only quantitative.

The left eye presented a phthisis bulbi, and the right showed a small corneal opacity,—the result of the injury when the left was destroyed.

The ophthalmoscope disclosed an old detachment of the retina projecting into the vitreous from the lower portion of the fundus, of a dirty grayish appearance, with atrophied, blackish, thread-like vessels.

It rolled up in waving folds, entirely obscuring the deeper portion of the chamber. As nothing could be done to improve or restore his vision, he was recommended to apply at the Asylum for the Blind.

SYMPATHETIC CHOROIDITIS.

H. McG., a man, æt. 60 years, in good health, by occupation a hostler, was struck in the left eye by a carriage-shaft, October 10, 1872, which caused much pain, inflammation, and total loss of vision, and procured his admission into the hospital.

There was much chemosis; a superficial slough of two-thirds of the cornea occurred, with hypopion, for which paracentesis at the lower edge of the slough was performed to evacuate the pus and relieve tension, and a solution of atropia was instilled often.

Pus reaccumulated, distressing symptoms returned, and the paracentesis was repeated; the slough deepened, and much pain supervened, for which the artificial leech was applied to the temple, and the slough gradually healed under slight stimulation by a solution of nitrate of silver.

Vision was destroyed in this eye, but was $\frac{20}{XX}$ of Snellen's in the right.

The patient now left the hospital without permission, and did not return until November 11, when the conjunctiva of the injured eye was found inflamed and thickened, and an anterior staphyloma forming. He complained of dimness in the right, hitherto healthy eye, and, upon testing this, V = $\frac{6}{C}$ only; and, as there was much pain in the left, the latter was immediately extirpated.

After recovery from the operation, the right eye was examined by the ophthalmoscope, and well-marked choroiditis found to the outer side of disk, irregular pigmentation, and white spots of sclerotic here and there, the result of choroidal atrophy, with a crescent forming at the margin of the optic nerve. The operation improved vision at first.

The patient was retained in the hospital under alterative treatment and observation, and now, April 1, 1873, has a distinct sclerectasia posterior, a slightly-cupped disk, with diminished capillary circulation, and an almost complete atrophy of the pigment throughout the fundus, with vision little more than quantitative.

TRAUMATIC RUPTURE OF THE URETHRA—HYPOGASTRIC PUNCTURE OF THE BLADDER—EXTERNAL URETHROTOMY—RECOVERY (De Bousseau: *Union Médicale*, 1872, No. 81; quoted from *Centralblatt für Med. Wiss.*, No. 36, 1872).—A mason, 52 years old, ruptured his urethra, by stumbling and falling. A few weeks subsequently, a stricture had formed so tight that the finest bougies would not penetrate it, and there was an almost complete retention of the urine. External urethrotomy was essayed, but the stricture could not be found, on account of the presence of so much thick cicatricial tissue; and, as most unfavorable symptoms of all kinds set in, puncture of the bladder above the symphysis pubis was resorted to, and the wound in the perineum was kept open.

On the fourth day after the first operation, the same was renewed, as follows: A curved sound was introduced through the wound in the hypogastrium into the bladder, and, guided by the finger placed in the rectum, into the neck of the bladder, and then into the urethra, until the instrument rested on the posterior side of the stricture. The incision was then boldly made through the stricture down upon the blunt end of the probe. The wound healed rapidly, and the recovery was complete.

Three similar cases of operation have been reported by Chopart, Baseilhac, and Voillemier.

LEBERT ON TUBERCULOSIS IN THE FEMALE GENERATIVE ORGANS.—Dr. H. Lebert (London *Medical Record;* from *Arch. für Gynaecologie*, vol. iv. part iii., 1872) has an interesting paper on this subject. From thirty-three observations, he has been able to follow the history of the reciprocal influence of pregnancy and tuberculosis. He concludes that tuberculization of the internal generative organs among women may be the principal primitive localization, or may coincide with pulmonary tuberculization, or finally may be secondary to this.

The malady described as tuberculosis of the neck of the uterus is not demonstrated; it represents most frequently a caseous degeneration of the epithelium of the glands of the neck. The influence of pregnancy and parturition upon tuberculosis shows itself most often between the ages of twenty and thirty years, more between twenty-five and thirty years, and even between thirty and forty years. When the tuberculous process exists in young women, it may be arrested, but generally takes on new development under the influence of pregnancy, often of the first, but sometimes later. It is exceptional that women who have formerly had tubercle resist the influence of repeated pregnancies; their infants are generally feeble and tuberculous.

Pregnancy generally moderates advanced phthisis, but the initiatory phases of tuberculosis follow their course without being hindered during the term of pregnancy. Abortion, pregnancy, and parturition accelerate in three-fourths of the cases the progress of phthisis. Pregnancy has no notable influence upon the localization and the form of tuberculosis. The sad influence of parturition shows itself especially in the cases where pregnancy had favored the development of tubercle. Women affected with tuberculosis have little milk; they cannot generally nurse; the children are weak, scrofulous, and, later, tuberculous.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 12, 1873.

EDITORIAL.

OUTSIDE INFLUENCE.

THE appointment of Resident Physicians at the Philadelphia Almshouse Hospital is prescribed to be by *concours*. The applicants are examined by the Medical Board of the hospital, and the result of the examination is accurately reported, by means of a system of merit-marks, to the Board of Guardians of the Poor, under whose control the affairs of the hospital are conducted. It would naturally be supposed that, if the examination means anything at all, it means that those candidates who obtain the highest marks should be, as a matter of course, chosen. Such in fact has been the case the last two or three years,—the highest on the list having been appointed by the Guardians. On a recent occasion the examination was duly held, —the number of vacancies being five,—and the report made; but a motion that the five candidates of highest merit should be declared elected was negatived by a very large majority.

A ballot was then gone into, and four gentlemen were chosen, to the exclusion of the highest applicant on the whole list; but on the second ballot he was elected by a bare majority. It appeared that there was outside influence used, and that letters on behalf of a certain candidate had been written to some, perhaps all, of the members of the Board of Guardians, at the instance of that power, scarcely "behind the throne," which, not content with shaping the legislation of States, is now grasping at the appointments of a poor-house.

Now, we submit that this is all wrong. It is wrong for the institution, since the object of the examination system is to secure for it the services of the *best* men as resident physicians. It is a wrong to the applicants, since they are led to believe that they depend for their success upon their merits alone. It is an insult to the attending staff, since they undertake to grade the candidates according to the amount of ability displayed by each one, with the sole object of guiding the Board of Guardians to a judicious selection.

If the *concours* mean nothing,—if the idea is that it is a mere revision of the action of the Faculties by whom diplomas have been granted to the young physicians seeking the residentships,—then let the system be abandoned, or at any rate remodelled, so as to be a consistent whole. It is by just such admissions of extraneous influences that fairness in scientific and professional competition is most effectually hindered.

A REMARKABLE BOOK.

OUR readers will, we trust, pardon us for digressing for a moment from graver themes, to refer to a work of fiction of unusual interest to the medical profession. The book itself—"Middlemarch," by George Eliot (Mrs. G. H. Lewes)—is a very remarkable one, its merits lying neither in plot nor in incident, but in the wonderful power of subtle analysis of character and motive, and of pithy expression of truth, which stamps its every page. Its chief interest to the physician, however, will be found in the fact that one of the leading personages in the story is a young and well-educated "general practitioner" in a small provincial town in England.

With singular accuracy and force the author has sketched his early bias towards the study of medicine; his hopes and disappointments; his ambitions and failures; his professional associations; the effect of his marriage, to a woman who could not appreciate any of his higher qualities or interests, upon his own development. The final catastrophe of his career in Middlemarch, most ingeniously conceived, is as admirably described.

Novelists have often introduced physicians among their characters, and sometimes made them play important parts in the evolution of their plots. When tested by the light of practical experience, however, the defects of these representations are often singularly absurd. Thus, Mr. Charles Reade makes a surgeon detect a depression of the skull, from injury, "just at the left of the *pia mater*." (!) So far as

we know, Mrs. Lewes has outdone all her predecessors in the *vraisemblance* of her medical hero and his incidents.

As a relaxation from the physical and mental strain involved in the practice of medicine, a certain amount of novel-reading is an invaluable resource; and we are sure that many a hard-working doctor will find himself the better for the perusal of the remarkable book to which we have ventured to devote these few lines.

THE FEE-BILL REPEALED.

AT their stated business meeting on the 2d inst., the College of Physicians of Philadelphia repealed that part of their By-laws relating to the Fee-bill. By this action, which took nobody by surprise, they did not set aside all rule as to the amounts to be charged for medical services, since there is on this point a general understanding in the profession. Nor did they by any means preclude the adoption at any future time, should experience show it to be desirable, of a substitute for the repealed tariff.

The established scale of charges being unsatisfactory, and the substitutes proposed being equally so, the substitutes were laid on the table, and the old tariff set aside. Every man is now at liberty, as indeed he was before, in our opinion, to place such value upon his services as he thinks his patients will be willing to acknowledge. This is as it should be; and we trust the unwritten law will be found a sufficient guide.

OUR London letter for this week has not been received.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—On the morning of the 1st of last December, I was summoned by D. Graham, notary public, to attend an inquest at the residence of the late Mrs. Eliza Collier, one and a half miles southeast of this place. Entered the house,—which is a frame building, eighteen by forty, southern front, front piazza and shed room, back way; all built of pine; about twenty years old. In the right-hand room, about nine feet from the fireplace, lay the remains—*head*, the bones of *left shoulder*, *outer* two-thirds of *left clavicle*, two or three upper *ribs*, and left *arm* and *fore-arm*, with the *hand*. The skeleton of *fore-arm* was lying along the chest with the hand, semi-flexed—as though it had been carried to the mouth—while drawn up under that piece of clavicle was the heart, about *half its natural size*. Under the ribs I found the left lung drawn up to the size of my fist, and looking like the upper leather of an old shoe which had been burned. Spine flexed upon itself, and pelvic bones; latter supported by the *partially burned sleeper*, while the head—face half upwards and towards the front door—lay on the floor beyond the burned opening; as I attempt to represent by the enclosed drawing. [The drawing could not be conveniently inserted here.—ED.] In the pelvic cavity was a bunch of *small* intestines *roasted*. On the ground beneath was the upper half of one *femur* and some few fragments of *ribs*; but, although I gathered up with a hoe the surface covering of the ground, there was no sign of phosphate of lime. The only sign of *flesh* was the face,—bloated, like the men who were blown up in the mines (military) at Petersburg, Va., so that her own daughter could not identify it,—and left hand. This is positively all that remained at daylight—when the burning floor was extinguished—of her whom the servant had left the night before in her usual health. I could have put it all into a small candle-box.

Medical Examination.—Occiput denuded to the superior line by fire, from which point I dissected off the scalp, and found ecchymoses—suggillations?—at a point midway between the eminence and posterior superior angle of left parietal, superficial bruise at anterior angle of left eye, and another just above the eyebrow, showing, by the grit thereon, that they were from striking against the floor. Pupils *perfectly* normal: I do not profess to be able to tell by the reflection, but certainly there was no appearance of quailing, as they are said to show from fear; there was no sign of compression or concussion,—nothing, in fact, that would justify my opening the skull. *Protruded* tongue seemed to be inflated, rough like sand-paper, and tied around—so to speak—at its roots by the constrictor oris. Opening the heart, I found the auricles empty, while the ventricles were filled with a mass, size of a walnut, about the consistency of a lump of prepared chalk, and Spanish-brown color, as shown by marks made therewith on the table. Strange to say, there was not a shade of difference between venous and arterial masses.

Evidence.—I find several bruises,—as shown the jury,—neither of which indicate violence at all; certainly not sufficient to have produced death. And, as the eyes are natural, together with the fact that the skull is entire, we conclude that there have not been any very severe blows on the head; that ecchymosis which I have pointed out to you is natural in the dead subject.

I have seen similar condition of the tongue in a man of General Casey's division, who was killed at Seven Pines. Dr. De Lean, General Lee's Medical Director, named it, but I do not remember any technicality by Dunglison, nor that it is pathognomonic. I have seen it in violent peritonitis from gunshot wounds of intestines,—once in a case of wound of bladder,—soldier under my care at Camp Jackson Hospital, near Richmond, Virginia. The absence of blood-stains *anywhere* precluded the idea of lacerated or incised wounds. She came to her death by fire; and the complete destruction, without leaving even the constant phosphate of lime from the bones, with such slight in-

jury to the house (*and most of that must have occurred after the body was destroyed*), especially in such a cold, dry time, together with the *positive evidence* that no other fuel, not even her wearing-clothes, was used; furniture, etc., all intact; bed showing that it had been occupied; candle *nearly entire*, and matches on the mantel-piece; no evidence of any unusual fire having been in the fireplace, but just the contrary, for the few remaining chunks were not scattered; nor did the abundant *cobwebs* show any new deposit of soot, as they would had there been much smoke in the room,—so far exceeds anything which I have seen (and I have seen bodies that had been exposed to the concentrated heat of four stories which were burned beneath them; and, as I learn from one of this jury, so far exceeds the destruction of a man whom he saw chained to a tree inside of a kiln of light wood, several banks thick, all saturated with spirits of turpentine before being fired), together with the previous history of the person, who, by the way, was about seventy-five years of age, brings me, notwithstanding the teachings of Dupuytren, Liebig, Bischoff, and others, to believe that it is a case of what may be truly called *spontaneous (?) combustion;* stranger by far than those of Devergie, in his work on "Médecine Légal." In some respects this case is very much like the one reported by Le Cat,—inasmuch as a party who was seen at the house after sun-down, on the best of terms, and, as I am assured, stopped (on his way from this place) there as late as 9 o'clock P.M., saying to his comrade that he was going to have a big hot whisky or ginger dram with the old lady, with whom he was going to work next year, is suspected of, or rather the Governor of the State offers a reward for his arrest, calling him the murderer of Mrs. Eliza Collier. Mrs. Collier's, however, differed from all other cases of *so-called* spontaneous combustion in one very important particular. She was the merest shadow of any living person I ever saw (I had reduced a dislocation of the left shoulder for her only a short while before, and remember that she was almost devoid of *visible* muscle). Again, she was some nine feet from the fireplace, and there was no burnt place between herself (where she was) and the fireplace. There was, however, another burnt place, where her shawl had been partly or entirely burned up, but it was some six feet from the other place,—rather towards the northeast corner of the room.

It is certainly a very strange case. I know but little—though of same name—of the old lady, save by report. She had property; had seen trouble from various causes; and *report* says she drank heavily; she lived alone, refusing to allow any of her family (and she had several daughters) to stay with her. As to actual *spontaneous* combustion of the body, I do not believe in any such; spontaneous is not the word; but there must have been some predisposing cause for such burning, and I trust you will be able to throw light on it.

I send you an unvarnished statement of facts, with full permission to cull anything therefrom which you may consider worthy of your most excellent journal. Hoping you will remember the haste in which it has been scratched, and pardon its very many deficiencies,

I am, very respectfully, etc.,

J. M. COLLIER, M.D.

ORION, GEORGIA, February, 1873.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, MARCH 13, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. H. LENOX HODGE exhibited *multilocular ovarian cysts* removed from a woman 26 years of age, by ovariotomy, on Wednesday, March 5, 1873. The patient was doing well when last heard from.

The cysts are very numerous,—some of large size containing others within. The fluid was thick and ropy, varying in consistence and color in different cysts. The specific gravity was about 1037. Upon application of heat and nitric acid it coagulated very firmly, showing a large quantity of albumen. A microscopical examination detected granular cells about the size of white corpuscles, and granules in irregular-shaped heaps.

The pedicle was about four inches long, about two inches wide, and one-fourth of an inch thick.

The other ovary was healthy, and no enlarged Graafian follicle detected; and yet three days after operation the menstrual discharge appeared, after an absence of nearly eight weeks.

Dr. R. M. BERTOLET asked for some further particulars with regard to the granular cells alluded to, whether they seemed to be provided with a cell-wall, and what was the character of their granular contents, whether they were coloring-matter or drops of fat.

Dr. HODGE replied that as to a minute explanation, he must leave that to the microscopists; but, as far as he could tell, the cells resembled the colorless corpuscles of the blood; and, if the latter has a cell-wall, these granular cells also might have a cell-wall. He thought that the granules they contained were neither fat nor coloring-matter. He believed they were the cells which Dr. Atlee, or rather Dr. Drysdale in Dr. Atlee's work on "Diagnosis of Ovarian Tumors," considers pathognomonic of ovarian tumors. Dr. HODGE professed to know very little about the histology of ovarian fluids. He thought Dr. Koeberlé, of Strasbourg, had made the most careful examinations with which he was familiar.

He thought that it was the inclination of all pathologists to consider ovarian cysts more or less connected in their development with the Graafian follicle; and he was therefore inclined to trace the contents of the cyst to an alteration in the original contents of the follicle, although he knew that cysts occur in the fibrous structures of the ovary, as well as in other fibrous structures.

Dr. JOSEPH G. RICHARDSON said that he had found these compound granular corpuscles in several cases of ovarian tumor; but they were generally larger than the colorless corpuscle, usually twice as great in diameter. He believed their granular contents fatty, and in their entirety they resembled the compound granular corpuscles found in inflammatory and other degenerative diseases of the brain. He had not been able to discover a cell-wall.

The PRESIDENT asked Dr. RICHARDSON whether he attached any importance to them.

Dr. RICHARDSON said they might be of value in determining ascitic fluid from that of ovarian cysts.

Dr. HODGE said that Spencer Wells, of London, Keith, of Edinburgh, and Atlee, of Philadelphia, all declare there is no real difficulty in distinguishing ascites from ovarian dropsy by physical signs and other means; but in distinguishing ovarian tumor from fibro-cystic growths of the uterus, if this cell exists in the ovarian and not in the fibro-cystic tumor, it must be a valuable aid to diagnosis.

Dr. JAMES TYSON regretted very much that these views should have been promulgated under a name so deservedly well known as that of Dr. Atlee. For he was satisfied that it was opening an elementary question in pathology long since settled, the effect of which can only be to mislead for a time those ignorant of the subject; for those who have had any comparative experience can scarcely be misled. He had enjoyed an opportunity, through Dr. Mears, of making a number of examinations of ovarian fluid derived from the cases of Dr. Atlee, and was perfectly familiar with the cell spoken of as the "ovarian cell," which is nothing more than the ordinary *compound granule-cell* formerly improperly called the "exudation corpuscle" or "inflammatory corpuscle" of Gluge, and for some time determined to be nothing but a fattily degenerated cell, in whatever locality found, and liable to be found in any locality. It is of course more frequently seen in situations where rapid tissue-change is taking place, either in inflammatory or non-inflammatory softening. Of the former, instances are seen in the so-called exudation of pneumonia or acute nephritis, as well as acute softening of nervous centres; and of the latter, examples are found in the chronic fatty degenerations of the nerve-centres, of the kidney, and, indeed, all fatty degenerations. Perhaps the most typical form of compound granule-cell is the colostrum corpuscle, which is the fattily degenerated epithelial cell of the milk-duct, and which by a further fatty degeneration forms the fat-globules of milk.

In ovarian cysts it is the fattily degenerated epithelial cell derived slowly or rapidly from the epithelial lining of the cyst, and is sparse or abundant according as the contents of the cyst are transparent and thin, or opaque and dense, or intermediate in both these respects. But it is also found, though of course in smaller numbers, and perhaps less marked in its degree of degeneration, in the most transparent serum from the pleuritic or peritoneal or any synovial cavity, when it is derived from the epithelial lining of such cavities. And when these secretions are altered in quality or quantity, the number of these cells is increased. Recently Dr. Tyson had tapped a patient with pleurisy in his ward at the Philadelphia Hospital, drawing off a large quantity of sero-purulent fluid, which, in addition to pus-corpuscles in different stages of degeneration, contained numerous typical compound granule-cells. So also, although present in limited number in the normal peritoneal fluid, in the altered fluid of ascites they are more numerous; and it is equally apt to occur in the contents of fibro-cystic tumors of the uterus.

Dr. JOSEPH G. RICHARDSON said that if the compound granule-cell is a fattily degenerated cell we would not be apt to find it in those fibro-cystic tumors which have no epithelial lining.

Dr. BERTOLET remarked that all these fibro-cystic growths have an endothelium.

Dr. J. EWING MEARS said he was glad to hear the discussion on this subject. It had been one of great interest to him during the past three years, and, through the opportunities kindly presented to him by Dr. Atlee, he had given much time to its investigation. He regretted exceedingly that he could not accept the views announced in the work of Dr. Atlee, to which allusion has been made, and which gives to the fluid of ovarian cysts a pathognomonic product in the so-called *ovarian cell*. No one would welcome the discovery of such a product with greater satisfaction than himself. He would regard it as a great advance in ovarian pathology, and it would render the diagnosis of ovarian disease both certain and easy. He had submitted to Dr. Tyson, and examined with him, fluids from ovarian cysts, and could agree with all that he had said upon the subject.

Dr. MEARS had examined specimens of the fluid contents from all varieties of cystic disease of the ovary, and he believed that by a simple analysis they could be separated into solid and fluid constituents: the former consisted of cells from the epithelial lining membrane of the cyst, and the latter was serum with a greater or less amount of albumen (in addition to that in the serum normally) derived from the cells which had undergone disintegration. These cells, undergoing fatty degeneration, were detached from the epithelial membrane, and their forms became altered. In the fluid of simple unilocular cysts he had observed the cells in the incipient stage of fatty degeneration, showing nearly normal forms with but few granules. In this variety of cyst the tissue-change is not rapid, and as a result the fluid is usually not very consistent,—about like serum,—and contains but few cells.

In multilocular cysts, on the contrary, where the degenerative change is very active, the fluid is found to be very viscid, and contains a much greater proportion of albumen, with great quantities of granule-cells and granular débris from the broken-down cells.

The physical properties, as well as the microscopical characters, are to be considered in distinguishing ovarian fluids from those taken from the abdominal cavity in simple ascites, in inflammatory conditions, or in fibro-cystic tumors of the uterus. Neither can be taken separately as positive evidence; together they are confirmatory, and become important aids in diagnosis.

OBITUARY.

DR. RENÉ LA ROCHE.

IN the death of Dr. La Roche, on the 9th of December last, the medical profession lost one of its most distinguished ornaments. Born in 1795, in this city, in which his father, a graduate of Montpellier, in France, and afterwards a resident of St. Domingo, practised medicine, he did not commence the study of his profession until 1817, having been for several years engaged in commercial business. He graduated at the University of Pennsylvania, in 1820. During the War of 1812 he was captain of a volunteer company in Colonel Chapman Biddle's regiment. Soon after graduation, he became connected with Dr. Chapman's Summer School, as it was familiarly called, and was one of the most active members of the "Kappa Lambda Association of the United States," under whose auspices the *North American Medical and Surgical Journal* was for several years issued. When this society ceased to exist, the Monday Evening Club—the first medical club, it is said, in the United States—was founded, consisting of Drs. Wood, Hodge, Meigs, Bache, Condie, Coates, Bell, and La Roche, with whom Dr. Bond was soon after associated, and, at a much later date, Dr. S. H. Dickson. Dr. La Roche was for a long time an active member of the College of Physicians, one of the original members of the Pathological Society, and at one time its president, and a member of numerous medical and literary societies at home and abroad. He had been president also of the State Medical, County Medical, and Philadelphia Medical Societies. As a contributor to the literature of his profession his

services are memorable, for he was not only the author of several voluminous treatises, but he was indefatigable in his researches on a vast variety of subjects, which, when published in the medical periodicals of the day, attracted universal attention by their erudition, clearness, and practical application. There was hardly a respectable medical journal in the country whose columns were not at some time or other enriched by valuable contributions from his pen, embracing not only original classical papers, but elaborate reviews. His large works on Yellow Fever and on Pneumonia were and are standard authorities on these interesting topics, being almost exhaustive in the amount of information embraced in them. He was always writing, almost to within a few hours of his death, and has left behind sufficient material for several volumes, on subjects which are not hackneyed, but in their originality exhibit the natural inclination of his mind to trace out new and unbeaten paths in literature. His posthumous writings include material for several volumes on Music and its Uses in Medicine, on Fevers, on the Plague of Athens, a History of Schools from the revival of medicine to the present time, etc. He had written a great deal on music, and was at one time the possessor of a very extensive and valuable musical library. His health had always been delicate, without the evidence of positive disease, and he died of prostration, after several months of feeble physical condition, with a mind calm and clear to the very moment of dissolution.

REVIEWS AND BOOK NOTICES.

NOTES ON ASTHMA: its Nature, Forms, and Treatment. By JOHN C. THOROWGOOD, M.D. Lond. Second Edition. Philadelphia, Lindsay & Blakiston, 1873.

The main object of this excellent little work is to discuss the treatment of that distressing malady, asthma; at the same time, however, a short but explicit description is given of its pathology, and the different varieties in which it occurs. The reader is referred for a complete history of the disease to the late Dr. Hyde Salter's monograph on the subject.

Our author teaches that the asthmatic paroxysm is due to spasmodic contraction of the bronchial muscles, and compares this to colic. Spasmodic asthma is looked upon as a pure neurosis, and is to be treated accordingly. The treatment most strongly recommended during the asthmatic paroxysm consists in inhalations of chloroform, nitrite of amyl, and the fumes of burning nitre paper. The author also advises smoking the leaves of the datura stramonium and datura tatula, but prefers the latter as being safer and more effective. As internal remedies during an attack, antispasmodics such as the datura tatula, belladonna, and chloral are the only articles considered worth using.

As curative means, climate and rigid attention to diet are deemed of primary importance. The patient is directed to eat but lightly, the main meal being early in the day, and supper not later than 6 P.M., consisting of bread and milk or a cup of cocoa or tea with plenty of milk. But little drink is permitted. However, two or three hours after dinner, some "toast and water or pale brandy and water may be allowed." By the way, why is it that so many English writers refer to "toast-water" as a beverage which it must be a privilege for a patient to quaff "*ad libitum*" ?

Speaking of diet, it strikes us that the amount of food allowed the asthmatic by Mr. Pridham, as quoted by our author, would not long sustain an ordinary man taking even a moderate degree of exercise. It consists of six ounces of stale bread, four ounces of meat, and a half-pint of tea or coffee in the twenty-four hours. This writer also permits the use of "toast and water" after dinner.

The medicines which Dr. Thorowgood has found of the most benefit are nerve-tonics, such as oxide of zinc, arsenic, quinine, phosphorus, and the salts of iron and silver. Arsenic and the oxide of silver seem to have proved most useful. Of course it is only for those cases of a purely nervous or spasmodic nature that such remedies are advised. The author has also found sulphur and the hypophosphites of soda, potash, and lime of great advantage in asthma of long standing.

We should regret very much being reduced to the necessity of administering to a patient the "oleum sulphuratum" of the Ph. Lond. 1824, "a brown viscid substance with a most unpleasant smell," or even the sulphuret of potassium, pills of which the writer admits to have a "disgusting smell."

Iodide of potassium is recommended where there is any structural change; and in cases of "bronchial asthma," *i.e.*, where there is inflammation of the bronchial tubes in addition to asthma, mercury is highly esteemed. The cases given as illustrative of the curative effects of this drug are not, however, entirely convincing of its value.

The use of compressed air in the treatment of the different forms of asthma is favorably spoken of, but no mention is made of the inhalation of pure oxygen. Dr. Andrew H. Smith, in the *New York Medical Journal* for April, 1870, quotes several cases of asthma where this gas was successfully used.

A chapter is added in this edition on laryngeal and tracheal dyspnœa, and one on "hay asthma" concludes the book. Change of air is considered the best treatment for the latter. Numerous other remedies are mentioned, as inhalations of ether and camphor, the spray of a solution of quinine (as advised by Helmholtz), and various snuffs.

The book is well and agreeably written, and notes of a number of cases are introduced to illustrate the disorder and its treatment.

WHAT WOMEN SHOULD KNOW. A Woman's Book about Women. Containing Practical Information for Wives and Mothers. By MRS. E. B. DUFFEY. Crown 8vo, pp. 320. Philadelphia, J. M. Stoddart & Co., 1873.

Exactly who Mrs. Duffey is, does not appear from this book. She certainly has not had a medical education, since she betrays ignorance of some of the commonest things taught to every student; and yet she has had some experience, some reading, and some acquaintance with professional men (and women). In the volume before us, there is certainly much that is sound and trustworthy; but there are many topics which are of vast importance, as for example the treatment of croup, that of abnormal presentations of the fœtus, and that of post-partum hemorrhage, which are discussed in a way that would give no adequate idea of their gravity. And there are not a few statements to which we could by no means subscribe.

LESSONS IN ELEMENTARY ANATOMY. By ST. GEORGE MIVART, F.R.S., etc. 12mo, pp. 535. London, Macmillan & Co., 1873.

The author of this little work, while he has intended it for the use chiefly of teachers, and for readers of either sex, not already acquainted with anatomy, has sought to make it answer also for students of medicine who wish to look into the relations existing between man's form and the structures of other animals.

He seems to have accomplished his task with ability and judgment, although, in our opinion, a combination of this kind is not the most useful form of publi-

cation. We should have preferred two books,—one an altogether elementary hand-book, for non-medical readers, and the other a full and comprehensive treatise, for the regular student of anatomy. The omission of all reference to the generative organs, while very proper in a school-book, will diminish the value of the work for those who are inquiring more deeply into the subject. The excellent typography and abundant illustration of this volume add greatly to its attractiveness.

GLEANINGS FROM OUR EXCHANGES.

Teissier on Bronchial Hemorrhage as a Cause of Pulmonary Phthisis (London *Medical Record*, February 5; from *Lyon Médical*, January 5, 1873).—M. Teissier brings forward some cases in support of the view that broncho-pulmonary hemorrhage may be an occasional cause of pulmonary phthisis. In the earlier part of the paper, the author alludes to what has been stated by other observers (Trousseau, Bricheteau, Graves, Jaccoud, Bouchard, and Niemeyer) in favor of this mode of origin of the disease. In quoting Niemeyer, he advances the teaching of this pathologist, that the irritation of the lung or bronchial mucous membrane by foreign bodies is an occasional cause of phthisis, and that of these foreign bodies coagulated blood is the most frequent; further, that in those cases in which very acute phthisis immediately follows an attack of pulmonary hemorrhage in persons previously healthy, the inflammatory disorganization of the lungs is determined by the presence of the coagulated blood.

In stating his own views, M. Teissier says that bronchial hemorrhage is accompanied or followed by active hyperæmia, which is capable of giving rise to caseous pneumonia, or even to tuberculosis, in persons *predisposed to phthisis*. Whilst admitting that bronchial hemorrhage is much more frequently a consequence than a cause of phthisis, and that it may occur in individuals otherwise healthy without producing any results, he maintains that in comparatively rare cases it undoubtedly plays an important part in the causation of this disease in debilitated or scrofulous persons, or in those in whom there exists the least tuberculous tendency.

The experiments of MM. Perl and Lipmann, which show that blood injected into the trachea of dogs and rabbits produces no other results than a slight amount of local emphysema and pigmentation of the epithelium, are, according to M. Teissier, no evidence that bronchial hemorrhage is incapable of inducing phthisis in man; inasmuch as in the latter there is presumably some disease of the bronchial or pulmonary blood-vessels, which is in itself a condition tending to produce more or less permanent congestion. No anatomical evidence, however, is adduced in proof of the existence of any vascular change.

In speaking of the results of his own clinical experience, the author states that he has met with cases in which hæmoptysis appeared to be the precursor and determining cause of phthisis. He gives an account of three cases.

The first case is that of a man, aged 40, who was the subject of hæmophilia. He had from time to time attacks of hæmoptysis, and in the course of two years he presented the physical signs of phthisis. The disease terminated fatally.

The second case is that of a healthy man, aged 45, in whom profuse hæmoptysis occurred whilst he was travelling in the mountains of Auvergne. The hemorrhage lasted for a few hours, and he soon regained his usual health. Two years later, the hæmoptysis returned, and continued at intervals for about three weeks, and shortly afterwards physical signs of pulmonary consolidation were for the first time discovered. Death ensued in three months.

The last case, which is the most conclusive, is one in which pulmonary hemorrhage, caused by external violence, terminated in phthisis. A robust and perfectly healthy man, aged 33, was injured on the right shoulder by the fall of a tree. He was simply bruised; there was no fracture or dislocation. The injury was immediately followed by very profuse hæmoptysis, and he continued to spit blood more or less for eighteen months. He then began to suffer from dyspnœa, cough, and expectoration; and a physical examination of the chest discovered commencing disease at the apex of the right lung. The signs of pulmonary disorganization gradually increased.

The author concludes by again stating that it is only in those in whom there exists some predisposition to phthisis, that hemorrhage can determine the disease; and adds that, even when hæmoptysis is a *consequence* of phthisis, the presence of the blood often greatly aggravates the disease, and tends to hasten a fatal termination.

Cohnstein on Determination of the Life or Death of the Fœtus (London *Medical Record*, Feb. 5).—Dr. Cohnstein (in *Arch. für Gynäk.*, vol. iv., 3d part, 1872) states that the information whether the fœtus is living or dead during pregnancy, but especially during parturition, is often of the greatest importance; and where hearing the fœtal heart and feeling the fœtal movements fail or are uncertain, ascertaining the temperature *in utero* will often very materially assist if not decide us in determining the question. It is a fact that the temperature of the fœtus *in utero* is higher than the maternal temperature, and experience proves that the careful introduction of the thermometer into the uterine cavity, between the membranes and the wall of the uterus, is unattended by harm. We have thus a ready mode of settling the question when it is otherwise doubtful.

Successful Employment of Propylamin in Acute Articular Rheumatism.—M. Dujardin-Beaumetz, in a recent communication to the Société Médicale des Hôpitaux of Paris, related the results of his trials of propylamin in acute and subacute articular rheumatism. They had been very successful; the pain had first diminished, then the movements became easier, and the swelling in the joints disappeared rapidly. The duration of the attack seemed generally to be greatly shortened, and, on an average, the disease was stopped in about eight days. Dr. Dujardin-Beaumetz generally uses the following formula: propylamin, ten to thirty grains; tilleul water (infusion of linden-tree leaves), three ounces; syrup of morphia, five drachms; essence of aniseed, sufficient quantity.

M. A. Béchamp (London *Medical Record*, January 29) read a note before the Paris Academy of Sciences, December 30, on the alcoholic and acetic fermentation of the liver, and on the physiological alcohol of human urine. The author has obtained from two litres of urine, from a man of fifty, enough alcohol to estimate.

At Kinkiang (on the Yangtse), Dr. Shearer (*Edinburgh Medical Journal*) has been using strychnia in cases of opium-poisoning, with a success which bids fair to rival the magnificent results obtained by Dr. Johnston at the Chinese Hospital at Shanghai from atropine.

An Anatomical Society has lately been founded in Madrid by Dr. Velasco, who is also the editor of a periodical, of which the first number appeared last month, —the *Anfiteatro Anatomico Español.*

MISCELLANY.

WOMEN AS PHARMACISTS.—From a notice concerning the employment of women in pharmacy, in the *Gazette Médicale de Paris* for December 28, 1872, it appears that after female doctors we shall have female pharmacists: the one necessitates the other, though we should have thought that the mistress of pharmacy would have preceded the doctoress. However that may be, the School of Industry for Women, established in Amsterdam in 1869 by the Society of Public Usefulness (*Société d'Utilité publique*), has already qualified five young women for the pharmaceutical profession, and is now engaged in educating seven others for the same vocation. Doubtless others will not be slow to follow this example. Already German societies, instituted to obtain means of existence for women, think of uniting to present to the Federal Council of the Empire a petition praying that women should be authorized to follow the profession of pharmacist, or, at least, that of dispenser. It seems that there is a complete dearth of dispensers in the little German towns, and especially in the country. The new measure which is demanded should have the effect of obviating this state of things.

A BRAZILIAN PATRIARCH.—According to the *Anglo-Brazilian Times*, at a recent census in Brazil, there was found living at Cape Frio, in the province of Rio de Janeiro, a man named José Martino Coutinho, who was born on May 20, 1694, and was consequently 178 years old. He was in perfect possession of his mental faculties, and complained only of stiffness in his knee-joints. The account states that he fought when young against the Dutch at Pernambuco, and that he remembered the principal events of the reigns of John V., Joseph, and Maria I. (*circa* 1750–80). He is said to have been married six times, and to have had forty-two children, and to be able to count in his descendants 123 grandchildren, 86 great-grandchildren, 23 great-great-grandchildren, and 20 children of the latter.

DR. EDWARD FLOURENS RIVINUS, who died at Hyères, France, on the 14th of February, was an extremely well-educated physician, and at one time practised medicine in this city. He was a man of property, and had retired from active professional life for many years. He was one of the managers of the Episcopal Hospital.

MAHOMET-ALI-BEY, an Arab surgeon, who recently cured the mother of the Khedive of Egypt of a serious malady, received from his patient a fee of five thousand dollars, and has been raised by the Viceroy to the rank of a Pasha.

THE suspension of the New York *Psychological Journal* is much to be regretted. It certainly did not owe its ill success to lack of ability in its editorship, or of interest and importance in the subjects to which it was devoted.

SIR HENRY HOLLAND is 84 years old, being the senior Fellow of the Royal Society.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending April 5, 1873, were 332; 182 adults, and 150 minors. 10 were of bodies brought from the country; making the mortality of the city 322. Among the assigned causes of death were:

Consumption of the Lungs	63
Other Diseases of the Respiratory Organs	48
Diseases of the Circulatory Apparatus	17
Diseases of the Brain and Nervous System	64
Diseases of the Digestive Apparatus	19
Zymotic Diseases	28
Typhoid Fever	6
Diseases of the Urinary Organs	5
Casualties	6
Cancer	4
Suicide	1
Debility (including "Inanition" and "Marasmus")	25
Still-born	8
Old Age	15

(The interments reported for the week ending April 6, 1872, were 418.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER. Max.	Min.	BAROMETER. (2 P.M.)
Mar. 30	53.5°	43.0°	29.84 in.
" 31	57.0	47.0	29.89 in.
April 1	59.0	39.5	30.17 in.
" 2	70.5	55.0	29.83 in.
" 3	64.0	43.0	30.07 in.
" 4	59.0	44.5	30.26 in.
" 5	64.0	43.5	30.24 in. (Thunder-storm.)

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 1, 1873, TO APRIL 7, 1873, INCLUSIVE.

COUES, ELLIOTT, ASSISTANT-SURGEON.—Assigned to duty, as Medical Officer and Naturalist, with the expedition for the Survey of the Northern boundary. S. O. 68, A. G. O., March 31, 1873.

BOOKS AND PAMPHLETS RECEIVED.

Text-book of Physiology, General, Special, and Practical. By John Hughes Bennett, M.D., F.R.S.E., etc. etc. With twenty-one Photo-Lithographic Plates. Small 8vo, pp. 606. Philadelphia, J. B. Lippincott & Co., 1873.

Family Thermometry: A Manual of Thermometry for Mothers, Nurses, Hospitals, etc., and all who have charge of the Sick and of the Young. By Edward Seguin, M.D. Crown 8vo, pp. 72. New York, G. P. Putnam & Sons, 1873.

First Decennial Catalogue of the Trustees, Faculty, Officers, and of the Alumni of the Bellevue Hospital Medical College, of the City of New York, from 1860 to 1871. Compiled by Frederick A. Castle, M.D., Historian of the Alumni Association. Preceded by a History of the College, from its Organization to 1872, by Leroy M. Yale, M.D., President of the Alumni Association. 8vo, pp. 66. New York, D. Appleton & Co., 1873.

The Logic of Medicine. By Edward S. Dunster, M.D. (Reprint from the New York *Medical Journal*, March, 1873.) 8vo, pp. 31. New York, D. Appleton & Co., 1873.

The Credit Guide. Philadelphia. Vol. II., No. 1. April, 1873.

Report of Commissioners appointed to Select a Site and Build an Asylum for the Insane of New Jersey. November 1, 1872. 8vo, pp. 15.

SATURDAY, APRIL 19, 1873.

ORIGINAL LECTURES.

LECTURES
ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

(Continued from page 436.)

LECTURE VIII.

STENOSIS OF THE LARYNX AND TRACHEA.

STENOSIS, or stricture, of the larynx or trachea occurs in the wake of inflammation, whether traumatic, idiopathic, or specific. It follows chondritis and perichondritis with discharge of the cartilage. It may be due to organization of effused products of inflammation, or to cicatricial constriction following the healing of inflammatory ulcers, or to loss of tissue from injury. It is most frequently met with in connection with syphilis, but occurs in tuberculosis also.

The symptoms of this condition are those of impaired freedom of respiration; and on laryngoscopic examination we recognize alterations of parts, or adhesions of parts, diminishing the calibre of the tube. Sometimes the vocal cords are adherent in more or less of their extent; sometimes the ventricular bands are adherent in the same manner; and sometimes the inner surfaces of the arytænoid and supra-arytænoid cartilages are adherent. Tracheal stenosis is usually the result of vicious cicatrization of ulcers. It cannot always be recognized on laryngoscopic inspection, but is rather inferred from previous history, existing symptoms, and want of evidence of stenosis of the larynx, or external compression of the trachea. Sometimes the condition can be determined physically by exploration with bougies. This condition is a very serious one; necessitating, as a rule, the performance of tracheotomy and the permanent use of the canula. If the stenosis exists low down in the trachea, below a point at which a tracheotomy-tube can be inserted, there is no reliable remedy, inasmuch as stricture of the trachea is hardly ever susceptible of dilatation. In some cases of this kind it has been suggested that a long tube might be introduced low down through an external opening, and the maintenance of respiration be secured in this way.

Attempts have been made to dilate the calibre of the larynx and trachea by means of metallic bougies; and with a certain amount of success in some instances, respiration being secured by means of the tracheotomy-tube. Since the use of the laryngoscope, various operations have been performed, previous to the dilatation, for the purpose of relieving adhesions or removing exuberant tissue, the knife or the galvano-cautery being employed for the purpose. After such operation, dilating forceps are introduced through the mouth, and the parts kept asunder for a few moments and stretched. Then the dilators are introduced several times a day. In some instances the dilating tubes have been allowed to remain for several hours, or for several days; but there is great difficulty in their use, on account of the trickling of saliva down their sides into the larynx. Trendelenburg has tried to obviate this difficulty by inserting small segments of dilators, secured by a strong ligature which is allowed to pass out of the mouth. The string is less liable to excite salivation, and a smaller quantity gains entrance into the larynx. The treatment is exceedingly tedious. When the constriction seems in part overcome, a tracheotomy-tube with a valve or ball in it may be used, instead of the simple canula. This is for the purpose of encouraging expiration through the mouth instead of through the tube. If this goes on well, the tube is closed after a while, and both inspiration and expiration effected through the mouth. If this, too, goes on well, the tube is withdrawn for a few minutes every few hours, and, after a while, for a few hours every day, until it is evident that respiration can be effectually carried on in the natural manner; when the tube is finally withdrawn. It often happens that respiration becomes impeded in a few days after the withdrawal of the tube, so that the old incisions have to be reopened, and the tube employed again; but in a few days more it may again be withdrawn, and perhaps permanently. All this time dilatation with bougies is carried on daily by the patient, who should be taught the manœuvre, which should be persisted in for a long time.

It is useless to employ dilatation if the constrictions or the adhesions have not been previously relieved by the knife or cautery; for the parts are elastic, and, though they may stretch on the introduction of a bougie, they immediately come together again on its withdrawal.

Where it is impossible to overcome the stenosis by the means indicated, it would be questionable, in cases where the voice is irrevocably lost, whether, under suitable circumstances, an operation would not be justifiable, having for object the clearance of the larynx for respiratory purposes only. It seems possible that the larynx could be divided externally, the mucous membrane raised, the offending structures stripped off down to the perichondrium, and the mucous membrane then replaced. If the constriction concerned the upper portion of the larynx only, access might be had to it from the side, by Malgaigne's operation of sub-hyoid pharyngotomy.

ASPHYXIA.

Asphyxia—suspension or interruption of the access of air to the lungs, stoppage of the respiration—sometimes demands the services of the surgeon. Asphyxia may be caused by inflammatory swelling; organic obstruction; cicatrization; direct violence, accidental or surgical; closure of mouth and nostrils; hanging and choking; foreign bodies in the larynx, trachea, pharynx, or œsophagus; in-

halation of noxious gases; spasm of the larynx, from whatever cause; impaction of the epiglottis; the entrance of water, blood, or other liquids.

The various methods of restoring animation and keeping up artificial respiration are too well known to call for repetition in this report. They were briefly demonstrated by the lecturer, who stated that in the only instance in which he had an opportunity to try Professor Richardson's method of artificial respiration by means of a special bellows arrangement, which he exhibited and explained, he found it insufficient for the purpose, and abandoned it for Sylvester's method, by which he eventually saved his patient. The importance of immediate tracheotomy in case of impending death—even in cases of foreign body in the pharynx—was dwelt upon, and various devices were mentioned for maintaining the patency of the wound without the use of the tube, until the cause of the asphyxia could be removed.

FISTULÆ OF THE LARYNX AND TRACHEA.

A fistula of the larynx or trachea is either congenital, or the result of an abscess, or traumatic injury. Very little annoyance usually exists in connection with this affection, other than that arising from the more or less constant presence of discharge. The existence of an internal opening communicating with the air-tube can occasionally be seen with the laryngoscope, or is detected by the injection of some colored liquid, or by the passage of a fine probe along the fistulous tract. The egress of air from the interior at once denotes that the fistula is complete, *i.e.* has an external and internal opening.

The site of the external or cutaneous opening of congenital fistula of the neck is nearly always constant in the region of the sterno-clavicular articulation at the inner or outer margin of the sterno-mastoid muscle. Congenital fistula of the larynx is sometimes double-sided: out of forty-six cases reported by Heusinger,* ten were found to exist upon both sides of the neck. A fistula of the œsophagus or pharynx, or one merely leading to the thyro-hyoid bursa, must not be mistaken for an incomplete fistula of the air-passages.

The deformity in the neck, the constant presence of the discharge, and the frequent imperfections of the voice, often render the patient desirous of undergoing an operation for obliteration of the fistula, or at least of its cutaneous opening; but, as a rule, it is less successful than similar operations undertaken for the obliteration of fistulæ of inflammatory or traumatic origin in other parts of the body.

Several different procedures may be resorted to for obliteration of the fistula of the neck, the choice being determined by the size of the fistula.

I. Simple suture may be used when the opening is small, with its borders covered by integument, and the edges drawn inwards. Dieffenbach† recommends that some inflammation be first set up in the edges by touching them with tincture of cantharides, before they are drawn together by sutures.

II. Twisted suture. This is employed when the opening is large enough to permit a view into the trachea. The edges are freshened by cutting out a small wedge of the cutaneous border, above and below; the borders are drawn forward with a hook and detached with a flat-bladed knife so far that they can be brought together from either side without any tension.

III. When there is great loss of substance in the trachea, it is covered with integument from the side of the opening. If the opening is a round one, the wound in the integument is made twice as long. The integument is loosened to the breadth of one inch on either side. The edges are confined by a row of twisted sutures. Then a straight vertical incision one inch and a half long is made in the skin on each side of the suture, at a distance of about three-quarters of an inch, which relieves the tension at once. The side-cuts are filled with charpie. In five or six days the needles are removed and adhesive plaster applied.

IV. When the opening in the trachea is large and the surrounding integument thin, the above procedure will not answer, as the thin borders of the wound afford too few points of contact. An elliptical excision is made, and the edges loosened, and then brought into perfect contact by several suture-pins. An incision two inches long is next made to either side, and the bridge of skin is still further and more thoroughly loosened. Both bridges are then pressed together by their subcutaneous surfaces; on either side a longitudinal cylindrical splint of stiff leather is placed, and two large pins are carried through these and the intervening bridges of skin. The double layer of skin is turned over so as to form a vertical wall to the opening. The splints are not removed until the borders are firmly adherent to each other.

V. Another operation is the transplanting of a flap. Velpeau‡ relates an interesting case of forming a flap and turning it over. This method is best performed, according to Basseran,§ by raising a flap of skin 1″ broad and 2″ long below the fistula, a little smaller above than below, and of sufficient length to readily reach the opening which it is intended to close. The flap should be dissected up with as much connective tissue as possible with it, but without laying bare the cartilages. The flap may then be placed in position in two ways.

1. When the greater diameter of the fistula is horizontal. The flap is folded together so that its tip does not quite reach its root, the cutaneous surfaces being in contact. It is better to unite the tip of the flap to its root by a simple suture. The flap is then turned upwards, but not rolled round, and thus fills up the fistula. In this way the raw surface of the flap is in part directed towards the cavity of the larynx, and in part forms the an-

terior wall of closure. A long needle is now thrust through the raw edges of the fistula and through the entire thickness of the flap. It must go through the posterior portion of the flap, and not merely between its two opposing surfaces. The flap then lies in the cavity of the larynx. The dressing is completed with ordinary sutures, adhesive strips, and bandage.

2. When the fistula is round, or its longest diameter vertical. Then the flap is rolled together in its entire length, so as to form a plug or cylinder, twisted, and its free end shoved a certain depth into the fistulous opening, no free space being allowed to remain between the raw surfaces.

M. Roux* has successfully pursued a new method. A catheter of a calibre equal to that of the inner fistula is inserted, and the integument brought around it by sutures; union by first intention generally follows, and later the internal laryngeal opening closes up by granulations, to which the presence of the obturator gives rise.

ARTIFICIAL OPENINGS INTO THE LARYNX AND TRACHEA.

A necessity for making an artificial opening into the larynx or trachea arises under the several circumstances which impede the free ingress of air to the larynx, and in which it is possible to remove the obstruction by operation through the opening, or to make an inlet for the air below the obstruction.

In acute cases, and where the opening is to be maintained for a comparatively short time, the operation usually performed, especially in the adult, is that known as laryngotomy, and consists essentially in dividing the crico-thyroid membrane. The cases suitable for this operation comprise acute laryngitis, œdema of the larynx, fracture of the larynx, the maintenance of respiration during the removal of a large or vascular neoplasm by laryngoscopic manipulation, and the extraction of small foreign bodies in the larynx.

The operation is usually an easy one, except in certain traumatic cases, or other cases in which there is a good deal of emphysema. The position of the crico-thyroid membrane is determined by the touch, the patient being either recumbent or semi-recumbent, and the parts rendered prominent by elevation of the shoulders; and a vertical incision from an inch to an inch and a half in length is made in the middle line, so that the middle third comprises the position of the ligament. The ligament is then freed of any overlying tissue not divided in the vertical incision, care being taken not to divide the middle thyroid artery, which may be in the way of the knife, and which is to be held to one side, or otherwise secured, as the case may be. The ligament is then divided vertically, or horizontally, or crosswise, according to the nature of the case. When the opening thus made is insufficient for the purpose required, the incision is carried upwards, so as to divide the intermediate plate of the thyroid cartilage to a certain extent; care being taken to avoid wounding the vocal cords.

In other cases the cricoid cartilage is divided; but it is well to spare this cartilage if possible.

Sometimes it becomes necessary to divide one or more rings of the trachea in order to render the opening large enough for the free play of instruments. Under these circumstances the operation is known as laryngo-tracheotomy.

Tracheotomy may be performed above the thyroid gland, or below it. It is well to avoid this structure whenever it is possible to do so. The operation may be expeditiously performed as follows: The patient being in position, and everything ready, the operator places himself at the right of the patient, and his assistant stands on the opposite side. The skin being made tense by the thumb and fingers, or pinched up into a transverse fold, at the option of the operator, a vertical incision is made, dividing the skin and fascia from the cricoid cartilage to within an inch or so of the sternum. The operator then raises the connective tissue on his side of the incision with the forceps, his assistant doing likewise on the other side, and the fascia is then divided, fold after fold. The veins should be held out of the way by blunt hooks, or, if this is impracticable, should be ligated in two places, and divided between the ligatures. The muscular structures are separated by the fingers and handle of the scalpel, until the trachea is exposed; the fascia being raised and divided in the manner described. The thyroid gland is held upwards or downwards by blunt hooks, according as the operator intends entering the trachea above or below it. If this cannot be done with safety, it is encompassed with two ligatures, between which it is then divided. Any large vessels crossing the thyroid must be ligated first, and then divided in the same manner. During the operation the field must be kept clear by sponging, and moderate hemorrhage restrained by small bits of ice enclosed in a cloth. When the trachea is cleared, and the place for incision is in view, the tube is drawn upwards and steadied by means of a tenaculum, and divided from below upwards as far as may be necessary, care being taken to penetrate the mucous membrane, and to avoid wounding the posterior wall of the trachea. Air rushes through the opening with a peculiar hissing noise, driving the blood and mucus before it. The edges of the opening are now seized with toothed forceps and separated, when the necessary hooks or tubes are introduced. These instruments should be warmed before their introduction.

The abnormal course of the blood-vessels sometimes divided in this operation may give rise to serious hemorrhage. This hemorrhage, even if venous, is by no means always restrained by opening the trachea, and thus permitting re-establishment of the normal circulation, although Trousseau and others have operated hundreds of times without ever being embarrassed in this way. It is therefore advisable, in all instances where delay is not evidently dangerous, to restrain the hemorrhage before opening the trachea. Occasionally the hem-

* *L'Union Médicale*, 1855, p. 129.

orrhage is insignificant, not requiring the slightest delay or the securing of any bleeding vessels. After respiration has become quiet, the necessary operation for which the opening into the trachea was made is proceeded with, or the tracheotomy-tube inserted, as the case may be. It will usually be found sufficient to separate the lips of the tracheal wound by means of a tenaculum introduced upon each side to guide the tube safely; though special dilators have been devised for this purpose.

The edges of the external wound are brought together by strips of adhesive plaster, except at the lowest portion, which is left patent for drainage. A piece of oiled lint is slit and slipped under the tracheotomy-tube, to prevent undue chafing, and the wound covered with a simple dressing. A piece of gauze is confined over the wound by adhesive strips, to protect it from dust and to modify the temperature of the inspired air.

As long as the patient is confined to his room, the temperature should be maintained at about 80° Fahr., and the air kept more or less saturated with steam, in order to lessen the risk of subsequent bronchitis.

A double tube should always be used, the inner tube being the longer. This inner tube requires more or less frequent removal, to free it from inspissated mucus, which adheres to it, at times, in sufficient quantities to impede respiration.

When the tube is permanently withdrawn, the opening usually closes in a few days without surgical assistance.

The lecturer spoke of the occasional performance of tracheotomy for the purpose of inserting a tube and occluding the trachea above and around it, so as to prevent the escape of blood down the trachea in the performance of operations in the mouth and larynx. He exhibited the apparatus devised by Trendelenburg for this purpose. It consists of a tracheotomy-tube which is encircled by a hollow cylinder of rubber, communicating with a tube provided with a stop-cock. Air being forced into this tube, the cylinder around the canula becomes distended into a complete obturator. There is also a special arrangement for administering anæsthetics through the canula. Trendelenburg and one or two other foreign surgeons had employed this apparatus with satisfaction; but the lecturer was unaware of any instances of its application in this country, and had had no personal experience with it.

The lecturer also referred to the production of emphysema after tracheotomy, a complication occasionally encountered, and of which sufficient mention is not made in the books; and he instanced a typical case of the kind still under his treatment, in which a marked emphysema had followed tracheotomy performed as low down as possible, a short time ago, for perichondritis of the arytænoids. On the day of the operation emphysema set in, and by night had extended down to the shoulders and as high as the zygomatic process, lifting the canula completely out of the trachea. An unusually long tube was substituted for the shorter one, and the emphysema began to decline the next day.

STRABISMUS CONVERGENS:

WITH SPECIAL REFERENCE TO ITS ÆTIOLOGY.

A Paper read before the Northern Medical Association of Philadelphia.

BY S. D. RISLEY, M.D.

(Continued from p. 439.)

DONDERS, finding this almost universal association of hypermetropia with strabismus convergens, could not escape the conclusion that they sustained to each other the relation of cause and effect: "Hypermetropia is indeed the primary anomaly, to be sought for in the structure of the eye, and originally proper to the organ; strabismus is the secondary condition, which does not arise until some years after birth." That hypermetropia is the cause of the deviation finds strong corroborative evidence in those cases seen in the very commencement of the deformity, during the stage of so-called periodical strabismus; for in these the fact that hypermetropia already exists is presumptive evidence that it precedes the deviation, and the additional fact that the correction of the anomaly of refraction removes the tendency to squint seems to leave no room for doubt.

October 10, 1872.—Howard F., æt. 8 years, was brought to me by his parents, with the statement that when he looked at his book, or intently at distant objects, he became cross-eyed, but that when around at play his eyes were straight. The ocular movements were normal in all directions. V = $\frac{3}{4}$ in each eye (Snellen $\frac{15}{XX}$), and he could read No. 1 of Jaeger's test-types no nearer than 6″ to the eye, while had he enjoyed emmetropia he should have been able, at his age, to read it up to 3″ readily. His distant vision was brought up to normal by convex glass of 24″ focal distance. After atropization his vision fell to $\frac{1}{4}$, and the determination revealed total H = $\frac{1}{10}$. I prescribed convex glasses to be worn continually of 20″ focal length ($+\frac{1}{20}$), which more than corrected his manifest hypermetropia. Six weeks later his parents returned with him, that I might see the result of my advice, which had proved entirely satisfactory, as there had been no tendency to squint since the use of the glasses.

The deformity usually commences about the time the child begins to use its eyes for near objects,—*i.e.* from the fifth to the tenth year; although it occasionally occurs earlier than this. I wish to dwell upon this point, so that when the mother calls attention to the fact that her infant "squints" it may not be passed over as a fact of but little moment. The stronger probability is in favor of the deviation being due to ocular paralysis from some intra-cranial cause than of its being a case of simple strabismus.

At first it assumes a periodical character, as seen in the case of Howard F., appearing only when the patient is intently regarding some object,—it may be only when reading or looking at some near object. At this stage either eye is used indiscriminately, while the other moves inwards. If the hypermetropia be not neutralized by the constant use of suitable convex glasses, the squint will generally soon become permanent, presenting all the characters of concomitant strabismus.

Parents bring their children with all sorts of stories regarding the cause of the squint. In looking over my notes I find the following. One child, æt. 5 years, with permanent convergent squint of one year's standing, had fallen, striking the side of his head corresponding to the converging eye against the marble doorstep. The mother says he has squinted ever since. The child had H = $\frac{1}{48}$. Another never squinted until after an attack of measles. Ophthalmoscope shows H = $\frac{1}{36}$. Another with H = $\frac{1}{24}$ had learned to squint at school by imitating a little playfellow. He had H = $\frac{1}{48}$. Many insist upon it that the children were born so. One mother thought the squint was produced by the cradle being placed so that in looking after her, while about her household duties, the child must turn its eyes always in the same direction. A fragment of black court-plaster worn on the temple corresponding to the squinting eye, for the purpose of "drawing the eye back," had failed to effect a cure: so she came "to have them straightened." The child had H = $\frac{1}{36}$. There is some plausibility in its occurrence after an attack of either of the exanthemata, first admitting the existence of hypermetropia; for the accommodative power must participate in the general exhaustion following a fever, and thus the tendency to excessive convergence would be increased in proportion to the inability of the ciliary muscle to perform its accustomed task. The idea of imitation seems to have gained some credence even among physicians. I am not prepared to deny that strabismus is ever thus produced; but it is more probable that a common cause has produced it in both parties,—the imitated and the supposed imitator. Hypermetropia is very prevalent, and frequently hereditary. I have myself repeatedly seen several members of the same family hypermetropic. It is in such instances that we would expect to find more than one member with squint, a common cause inducing it. That such is the case I have had repeated opportunities for verifying.

How far the association of a non-squinting hypermetrope with one who squints may influence a tendency to deviation already existing, I am not prepared to say, but can readily conceive how it might determine a squint which, without such influence, might never have existed.

At the onset of the affection the shortening of the internal recti muscles seems purely dynamical; but later, after the deviation has become permanent, one eye being used invariably for fixing, it passes over into an organic change, hypertrophy resulting from the excessive task to which they are subjected, and the shortening becomes permanent; not of one but of both internal recti.

From this fact of organic shortening of both muscles we would be led, *a priori*, to anticipate but little from any treatment for its cure save from tenotomy, and that not of one but of both muscles. That both muscles—that of the undeviated as well as of the deviated eye—should be shortened, might be anticipated. In the first place, the hypermetropia can be best overcome by a strong convergence, on account of the increased power of accommodation thus afforded: moreover, in order to throw the image as far as possible from the macula lutea of the deviated eye, that, falling upon a more peripheral and less sensitive portion of the retina, it may the more readily be suppressed, the object is held to the side corresponding to the deviated eye. From these two circumstances the internal rectus muscle of the fixing eye is also kept in relatively strong contraction. By this effort, too, the degree of deviation of the squinting eye is relatively increased.

So long as the strabismus remains as alternating squint, the acuteness of vision is not lowered; but no sooner does the deviation become constant than the affected eye begins to suffer a diminution of vision, which rapidly becomes more and more marked. In a child between five and six years old who had begun to squint one year before, I found the acuteness of vision reduced to one-half. One month after tenotomy, however, the vision was normal in each eye.

This diminution may go on from a mere shade of difference between the eyes to an almost total loss of vision. There are some things about this loss of vision in the squinting eye which are somewhat contradictory. After the acuteness has become considerably diminished, it will be found difficult to induce the patient to fix an object with the deviated eye when the other is covered, or, when attempting to fix with it, he will be unable to recognize the largest type at any distance. He persistently refuses also to see double images even of a bright object, as a lighted candle. From these experiments one would be led to conclude that vision was entirely abrogated. That such is not the case, however, I am led to infer from the fact that we do not observe in such persons the peculiarities of one-sided vision. The man who has had one eye extirpated feels sadly the loss of the member, and complains that he must turn himself in order to see things on the side corresponding to the lost eye. He will tell you he never feels safe at the street-crossing, lest a team drive upon him unawares. Strabismic patients never make like complaints, however, and seek surgical aid for relief from the deformity alone. There is no discoverable organic change in the retina in these cases. That we can sharpen our senses by a strict mental attention is a fact of which we see constant proof, and that by a psychical exclusion we can also set aside physiological sensibility is well illustrated in these cases of strabismus. As in the case alluded to above, however, after the axis of the deviated eye has been forced by tenotomy to resume its parallelism, so that the image will once more fall upon the macula lutea, the acuteness of vision may be greatly improved, or, if the exclusion has not been of too long standing, may even regain its normal sharpness.

A case occurred to me which illustrates forcibly this point:

H. M., æt. 19, had had tenotomy performed on both sides in 1869 for the cure of strabismus. I saw her for the first time a year and a half later. She then had a permanent convergence of the left eye, measuring $3\frac{1}{2}'''$, and vision of $\frac{1}{10}$, while in the right or fixing eye there

was for distance a normal acuity of vision. The patient stated that for a few months after the operation the eyes remained "straight," and then the deformity rapidly returned, but changed sides, the opposite eye becoming the deviated one. At the time of the first operation the left or fixing eye was the good one, while she was "almost blind" in her right.

She had but little manifest hypermetropia ($H = \frac{1}{48}$), although, after thorough paralysis of the accommodation, a total hypermetropia of $\frac{1}{12}$ was revealed in each eye. Tenotomy on both sides was repeated, and positive glasses of $\frac{1}{12}$ given to be worn constantly, with instruction to exercise the left eye alone for an hour or two daily on the finest print that could be recognized. Three months later there was no return of the convergence, and the acuteness of vision had come up from $\frac{1}{10}$ to $\frac{3}{4}$.

In strong contrast to this is the case of an Irish girl, æt. 17, who consulted me in June, 1871, for marked convergence of the right eye which had lasted since early childhood. She came seeking relief from the deformity. She had $H = \frac{1}{10}$ in the deviated eye, and was only able to count fingers with difficulty at a few feet with a correcting glass. In the fixing eye there was normal acuity of vision, with the glass, which corrected the existing hypermetropia.

I performed tenotomy, which corrected the deviation; but a year later there was no improvement in the acuteness of vision in the formerly deviated eye. How faithfully she had obeyed my injunction to exercise the eye I cannot say. There was no longer any tendency to squint.

Strabismus should not be regarded as a mere deformity, and the operation for its relief as for a mere cosmetic effect. Permanent strabismus means, sooner or later, the more or less complete loss of vision in one eye; hence it is a condition demanding treatment as positively as an iritis or keratitis, and it should be thus represented to patients, who invariably regard it only as an unfortunate deformity.

The question naturally arises here, When should the operation be performed? I think the sooner after the development of permanent strabismus the better; for why should we wait until the sharpness of vision is diminished? There are other questions involved, however, which have caused some to hesitate, and even to advise the parents to have nothing done at present, but after a few years, when the child has gained in years and discretion, to return. It is true that after the operation the same cause is acting to reproduce the affection as was active at first in its production; and that there is a marked tendency to its recurrence we saw in the first part of this paper. The only way, in fact, to insure against the return of the deviation is to correct the optical defect which is so active in its ætiology, by prescribing proper glasses. Now, there is an obvious difficulty in the way of prescribing glasses for young children; yet in the case of Howard F., æt. eight years, with strabismus alternans, I did not hesitate to do so, rather than to allow the deviation to become permanent. In one case I operated at the fifth year. The deviation, although of but one year's duration, was fast becoming permanent, and already there was diminished sharpness in the deviated eye. The parents, however, were informed of the liability to the return of the deformity, and were carefully instructed to bring the child back if any tendency to relapse should at any time manifest itself. The acuteness of vision in the deviated eye might be preserved by persistent daily use of the deviated eye, compelled by keeping the opposite eye closed or by paralyzing its accommodation repeatedly by atropia. Binocular vision is so important that too much cannot be done to preserve the function of both eyes intact. I would not hesitate, then, to operate even earlier than the fifth year, if a case of permanent strabismus should present itself at so tender an age.

After what has been said of the cause of strabismus, the justice of my remarks regarding the claims to unvarying success made by some, and the rude denunciation of those who were sufficiently honest to acknowledge failures, I think will be no longer doubted. Hypermetropia was not yet understood; and that there should be no return of the deformity in a certain number of cases while the original cause still existed, I am scarcely willing to admit. That the deviation is frequently reproduced, we have abundant evidence in the experience of the earlier operators. I have also had frequent opportunities to observe the recurrence of the affection in cases operated upon in this city.

The case of H. M. is an illustration of this. Out of eight cases from a charitable institution in this city, operated upon at one sitting, no regard being paid to the optical condition, but one has proved at all satisfactory. In six cases, taken from my private practice, which I have been able to follow up for six months, for whom glasses were prescribed, in but one is there any tendency to a return. This patient was a lad of fourteen years, who, in consequence of the gibes of his schoolmates, persistently refused to wear his glasses. Six months later the deviation was as great as before the operation, which at first had been perfectly successful.

In cases of permanent convergence, the degree of hypermetropia should be carefully determined, with a view to correction by means of spectacles; afterwards, tenotomy of one or both internal recti. No new principle in the operation has been enunciated since the days of Stromeyer. Its details have been rendered less cumbersome, however, and experience has taught us how to regulate the extent of the operation.

The object to be attained is to cut the tendon of the muscle as near its insertion in the sclerotic as possible, and secure its re-attachment at a point farther back upon the globe,—the extent of the retraction to be controlled by the extent of laceration in the capsule of Tenon.

1438 North Thirteenth Street, Philadelphia.

COFFEE AND SULPHATE OF QUINIA.—M. Briquet considers the common practice of administering quinia in coffee open to much objection. He alleges that the tannin in the coffee coalesces with the quinia, forming a tasteless and insoluble and almost inert salt,—the tannate of quinia,—from which the stomach has as much difficulty in extracting quinia as from powdered bark. It is, he thinks, one of the worst preparations of quinia.

TWO CASES OF RETAINED FŒTUS SOME MONTHS AFTER THEIR DEATH,

AND TWO CASES IN WHICH PLACENTAS WERE RETAINED A GREAT LENGTH OF TIME AFTER THE EXPULSION OF THE FŒTUSES.

BY E. P. ALLEN, M.D.

IN the month of November, 1845, I was summoned to see Mrs. M. C., who was reported to have lock-jaw, or tetanus. I learned from her husband that she was thirty-five years of age, and the mother of four children, and had until two months since enjoyed comfortable health, though never very strong; that seven months before, she had become pregnant, without unusual symptoms until she had gone five months, when she felt unwell for a few days, and in a short time all motion of the child ceased. Her breasts became flaccid, and her abdomen subsided to its natural size. Her health became poor, and she consulted a physician, who told her that her child was probably dead, and she would be in labor soon, and get through without trouble, and then she would soon regain her health. Labor did not come on, and she steadily declined. Her jaws began to be stiff two days before, and steadily grew worse until that morning, when they became immovable. They could not be separated at all by any force safe to use; yet she had little pain, though an uncomfortable stiffness was felt. She was thin in flesh, and countenance pale and anxious; appetite poor, and bowels constipated. No one would have suspected from her appearance that she was pregnant of a seven months' child, or even of a five months' child. She was ordered to take an ounce of castor oil to unload the bowels, which she was able to suck through a cavity made by extracting a tooth some time before. The oil produced a copious evacuation in four or five hours, and was followed by labor-pains, which soon became regular, and she was delivered about two o'clock on the following morning of a fœtus apparently of about five months' growth, though greatly shrivelled and emaciated. The liquor amnii was quite dark-colored, but had little or no fœtor.

I have never been able to satisfy myself of the cause of the death of the fœtus.

The mother recovered slowly by the use of tonics and laxatives; though it was four weeks before she had the free use of her jaws. They were firmly closed ten days, when they gradually relaxed. She has since borne children.

I suppose the physiologist would assign the cause of the tetanus to the settling of the uterus into the pelvis, and with its enlarged dead weight producing undue pressure upon the nerves in the pelvis, causing a reflex action of the motor nerves.

Case II.—On the 25th of last November I was called to see Mrs. C., who was threatened with an abortion. Mrs. C. is thirty years old, and had always been regular as to time with her menses, though suffering slightly from dysmenorrhœa up to the 1st of October, since which they had not made their appearance. This being the first time she had ever missed, she was satisfied that she was pregnant, and, from the pains felt in her back and low down in front, and their paroxysmal character, believed she was about to miscarry. Her pulse was quick, skin hot, and she was evidently suffering a good deal of pain.

She was ordered to take a quarter of a grain of morphine every three hours, and cold acidulated drinks, and to keep her bed until she was free from pain. The next day she was nearly free from pain, but complained of feeling sore all over, as she expressed it. She was advised to keep her bed until she felt well, which was strictly followed four or five days, when she felt well enough to be up and mingle with her friends. I heard no more of her until the 13th of March, when I was called to see her, and found her again in pain, and some show evidently about to miscarry. Morphine was ordered, and rest, as before. In two hours she was free from pain, and felt so well that she took a short ride in a carriage, contrary to my advice, the same evening; yet she remained well until the evening of the 16th, when she was suddenly taken with severe labor-pains. I saw her at two o'clock on the morning of the 17th, and found her in active labor, with the os uteri so much dilated that I thought it useless to attempt to arrest the labor. Her pains continued, and were quite severe until four o'clock A.M., when she was delivered of twins, the placentas following soon after. The fœtuses appeared somewhat shrivelled, and did not look to be more than of six or seven weeks' growth, and were about the size I should have supposed them to have been at the time of the patient's first sickness, which was three months and twenty days before. The membranes having remained intact, there was no fœtor nor decomposition. No perceptible influence on the health of the patient was observed, excepting an occasional feeling of weakness, which lasted but a short time.

Dr. Ely, of Burlington township, related a case of retained placenta last September before the Bradford County Medical Society.

A woman miscarried, and the fœtus appeared to be of about four months' growth. The doctor was not present at the time; but, the placenta not coming away, he was called some hours after to remove it. On making an examination, he found the umbilical cord had been broken off within the uterus, and the os quite firmly contracted, and there was little or very slight hemorrhage. He concluded not to attempt to remove it, as there were no urgent symptoms. Supposing that the uterus would after a little time contract upon its contents and expel it, he directed the family to send for him if pains came on, and left. He heard no more for about five months, when he was called to the lady, who was in labor. In a short time he delivered her of an after-birth fresh in appearance as if immediately preceded by the birth of a child. The parts attached to the uterus were evidently not separated until the labor for its expulsion took place. No unusual fœtor was observed, nor had there been during the carrying the retained placenta, excepting a few days after the expulsion of the fœtus. The woman made a good recovery. Dr. Ely believed the expulsion of the placenta was at the full period of gestation; and had not the fœtus, from accidental or intentional causes, been previously expelled, it would have been born at that time.

Dr. G. F. Horton, of Terrytown, related a case at the same time where a placenta was retained several months without hemorrhage or much inconvenience to the patient, but could not say that it was carried to what would have been the natural period of gestation.

The writer is well aware that fœtuses are occasionally carried a few days, or perhaps two weeks, after they are dead, and that placentas are retained after abortions a number of days; but it is very unusual for them to be carried months, as in the above cases.

ATHENS, PA., April 5, 1873.

BLEEDING IN CERTAIN CASES OF PUERPERAL ECLAMPSIA.

BY RICHARD A. CLEEMANN, M.D.

IT is evident to the reader of current medical literature that bleeding, as a remedy in disease, is emerging in some degree from the disrepute into which it has of late years so deeply fallen. Especially is this the case where are concerned certain morbid conditions, of which the pathology is doubtful, but which have among their characteristics sudden and profound brain-disturbance. In such a category may be placed the puerperal state marked by the occurrence of convulsions; and three cases of this are recorded below as having a bearing upon this renewed advocacy of the lancet.

Case I.—I was called up on the night of May 24–25, 1868, to visit a primipara, said to be suffering terribly in her labor. The screams of the unfortunate woman—so loud as to have attracted two policemen under her window—were heard as we approached the house. Entering the bedroom, I found a young irregular practitioner of the neighborhood tugging at his forceps, applied over the child's head, which already occupied the cavity of the pelvis. The patient was a small, pale, black-eyed woman, of nervous temperament. She was attempting with great vigor to toss herself about, while uttering the loud cries already alluded to. It was said she had been seized with "spasms" before my arrival, though now I observed none of the consecutive symptoms. To shorten her intense suffering, I determined to use my own forceps at once, but had only time to adjust one of the blades, when, a strong contraction of the uterus taking place, the head of the child passed the vulva, the body and limbs soon following. After a certain time the first-called accoucheur attempted the delivery of the placenta—as I noticed too late—by traction on the cord, which ruptured just as the poor woman, with a loud cry, fell into a frightful convulsion. When the muscular contortions had ceased, the afterbirth was removed without difficulty by the hand introduced into the cavity of the uterus. Scarcely was this accomplished when, the patient starting wildly up, the blood poured out of the vagina like water from a hydrant. This was, however, the end of the trouble; the contraction of the uterus was soon assured, and the patient left quiet in bed. I did not see her again for several months, but learned that she recovered without a bad symptom.

The probable determining cause of the spasms in this case was uterine irritation, which ceased with the emptying of the womb,—quickly and easily accomplished at this period of the labor. The apprehension of cerebral effusion, aroused by the mental excitement, vanished with the opportune flooding instituted by nature.

Case II.—I was summoned in great haste at eleven A.M., January 21, 1871, to see Mrs. McT., multipara, with the explanation that she was suddenly attacked with convulsions, having been delivered the night previous, after an easy labor, of a child at full term. My patient proved to be a strong-looking woman, of nervo-sanguine temperament, of about twenty-five years of age. Three paroxysms of convulsions had occurred before my arrival, and she now lay comatose. Almost immediately another spasm of considerable violence, accompanied by frothing at the mouth, took place, and then another. The congested skin of the patient and the much-distended veins, that were like black tortuous cords twisted underneath, suggested dangerous vascular repletion. Her arm was tied up and a lancet plunged into a vein at the flexure of the elbow; the prick of the instrument caused a start from the patient, and a full stream of blood spurted forcibly from the aperture,—twenty ounces, judging by the eye, being soon abstracted. Placing a finger on the wound, I was watching the effects of the measure, when another convulsion took place: the finger was at once removed, but no blood flowed till the muscular disturbance had ceased, when again a full stream poured out; after about ten more ounces of blood had been allowed to escape, the patient became quite blanched in appearance, and the diminished force of the jet of blood showed a decided influence on the circulation. During the following one and a half hours the condition of the patient improved, and she seemed about to return to consciousness, when another convulsion supervened. She had had twenty grains of bromide of potassium in two doses meanwhile, and now a cloth saturated with chloroform was held over her nostrils till the muscular movements were discontinued. In a short time another spasm occurred, and before long another, and again another. A half fluidounce of turpentine in enema was now given. After about ten minutes had elapsed, the patient gave signs of great discomfort, moving her limbs and endeavoring to change her position: this uneasiness was relieved by an evacuation from the bowels, which was soon followed by another. After this there were no more convulsions, and the patient gradually regained consciousness. She experienced at first transient headache, and twitching of the hands was noticed. She was oblivious not only of the supervention of the eclampsia on her labor, but even of the birth of the child, which, as above stated, had taken place many hours before their occurrence. The next day I found my patient very cheerful, and in excellent condition; she progressed favorably in every way, and her breasts filled with milk in the usual time.

The appearance of her husband in a drunken condition immediately determined the convulsions of the last patient, a mental impression the disturbing effects of which might be expected to be transient, and demanding little treatment now that the labor was completed. The venesection practised, as stated above, was directed against the marked vascular repletion, which threatened dangerous congestions; and the quickly fortunate termination of the case shows that such a measure was not contraindicated by extreme hydræmia. In regard to the effects of the bleeding on the muscular disturbance, it may be plausibly said, according to the ingenious theory expounded by Prof. Joseph Carson (*Am. Jour. Med. Sci.*, April, 1871, and this journal, number for November 15, 1871), that the venesection was carried too far, and, by predisposing to syncope, was chiefly responsible for that second series of convulsions which occurred one and a half hours after the first was completed; but, as we see constantly the most violent eclampsia in children and epileptics, followed by no immediate bad effects, the criticism, in view of the greater danger of cerebral or pulmonary extravasation, is of little value. The happy sequence of the exhibition of the enema of turpentine, an arterial stimulant, lends its support to this view of the agency of syncope in the mechanism of convulsions; and in this connection it is worthy of remark that the failure of the blood to flow from the open vein during the muscular contortions, immediately succeeding the

first bleeding, is opposed to the generally received description of puerperal eclampsia, as regards the circulation, namely, that the "carotids beat inordinately," and that the pulse "increases in velocity as the intensity of the fit becomes greater." (Ramsbotham.)

Case III.—I was consulted January 27, 1872, by Mrs. H., a native of France, of sanguine temperament, aged about 38 years. She had been married twenty months, menstruated once afterwards, then had an abortion at three and a half months. The catamenia at the succeeding period were normal, but at the next nisus there was profuse hemorrhage, which recurred after three weeks. At the following three periods the menses were natural, the flow being scanty at their last appearance.

June 22, 1872.—It was calculated that she was now near the close of the seventh month of pregnancy. She came to see me about œdema of the feet, and I noticed that her hands and face also appeared puffy. Her calls to urinate were frequent, with a more copious discharge than usual, according to the patient's own estimate. Inquiry developed that there were also stiffness of the muscles, sensations of fulness in the head on stooping, and wakefulness; but these subjective symptoms occasioned but slight annoyance; the appetite was good, and the bowels were regular. Her urine, tested with heat and nitric acid, gave a small deposit of albumen, not sufficient, in an ordinary-sized test-tube that had been half filled with the urine, to occupy the convexity of the end. During the succeeding five days the condition of the patient did not improve, malaise and wakefulness occasioning more distress. After this time (on June 25) the patient complained of pain in the back of the neck and shoulders, and in the throat, also of burning sensations in right and left hypochondria; lying down brought on coughing, but the breathing was not embarrassed, and a clear note was yielded to percussion; the respiratory murmur was, however, of higher pitch than normal. The patient seemed to suffer intensely, and was very desponding, declaring incessantly that she should die. Remedies afforded but little relief, and at about 9 o'clock P.M. she fell into convulsions. Two paroxysms occurred before I reached her, within an hour, and at the expiration of that time another took place. An eminent obstetrician, who had been sent for in my absence, arrived shortly after myself, and gave me the benefit of his advice. Venesection was decided upon, and about twelve ounces of blood were taken from the arm. The operation was rather unsatisfactorily performed, owing to the thickness of the integument which obscured the position of the chief veins. The patient became subsequently less restless and more conscious, but after about five hours' interval (at 4.40 A.M., June 26) another violent convulsion took place, in which the patient's tongue, notwithstanding precautions were taken, was very much lacerated, the wound bleeding quite freely. She rallied once more after this, and was complaining from time to time that she was smothering ("*J'étouffe*"). Finally at 8.15 A.M. there was again muscular contortion, in which the patient's life ended, blood now issuing copiously from the nostrils.

In the treatment of this case, acetate of iron in the form of "Basham's mixture" was given when relief was first sought; afterwards jalap and bitartrate of potassa were also prescribed. On the day of the supervention of the convulsions, before their occurrence, three stools had been obtained, but, as they were feculent and it was desired to eliminate some of the water of the blood, elaterium was exhibited; the hydragogue was, however, rejected from the stomach, an evacuation from the bowels being afterwards procured by enema. Compound infusion of senna was then resorted to. For the pains an anodyne liniment was used. The bleeding practised after the convulsions occurred has already been alluded to; in addition, at this time, suppositories of belladonna and assafœtida were administered, and carbonate of potash and chloric ether given.

The immediate cause of death in this case seems to have been pressure upon, or laceration of, the medulla oblongata, the congestion of the upper portion of the spinal contents, betrayed by pain in the neck, shoulders, and sides, as in beginning cerebro-spinal meningitis, advancing till that great nerve-centre was fatally involved. Accepting this causation, it is thought that a large and rapid bleeding such as that practised in Case II. would have been of immense advantage. The surface of this patient did not present the same evidences of vascular fulness as that of the one in the case just alluded to; but this may have been owing to her thick white skin, so commonly found among the French, which would mask sanguineous plethora to the eye. Her subjective symptoms of wakefulness and fulness of the head on stooping pointed to that condition.

Oulmont on Treatment of Mercurial Tremors and Paralysis Agitans by Hyoscyamine.—Dr. Oulmont (*Gazette des Hôpitaux*, Jan. 11, 1873) considers that, although the results obtained by the treatment of neuralgia by hyoscyamine are satisfactory, they are neither more marked nor more rapid than those obtained by the use of opium or belladonna. In nervous diseases characterized by trembling, such as mercurial tremors, and paralysis agitans, marked benefit attends its employment, relief or cure being effected by it after all the other usual remedies, such as iodide of potassium, tonics, electricity, sulphurous baths, bromide of potassium, opium, etc., have failed. Four cases of tremors, treated with hyoscyamine, were cured, and two relieved; and two cases of paralysis agitans were relieved. In mercurial tremors he begins with a dose of two or three milligrammes of hyoscyamine daily, and gradually raises it, notwithstanding dryness of the mouth, etc., to twelve, or even seventeen, milligrammes daily. As the trembling ceases, the dose is gradually diminished. In paralysis agitans he gives six milligrammes daily, at first, and gradually raises the dose to ten.

Little on the Use of Digitalis in the Failing Heart and Delirium of Acute Diseases.—Dr. Little (*Irish Hospital Gazette*, Jan. 15, 1873) recommends the use of digitalis in febrile cases in which stimulants are either not well borne or are contra-indicated, as, for example, in most cases where renal affection is present. He has given it in more than twenty cases, including six of typhus and one of rheumatic fever, the remainder being cases of enteric fever. He usually gives half-drachm doses of the tincture every three or four hours, rarely every hour, and discontinues the medicine when the pulse falls to eighty. Along with the digitalis he gives wine and brandy. In one case of rheumatic fever where stimulants could not be borne, he used tincture of digitalis alone. After several doses nausea occurred. The tincture was therefore discontinued, and a hypodermic injection, composed of one-eightieth of a grain of atropia, one-fortieth of a grain of digitalin, and one-fourth of a grain of morphia, was substituted. The patient eventually recovered.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 19, 1873.

EDITORIAL.

GRATUITOUS ADVICE.

THE letter signed "Struggling Practitioner," which appeared in our issue of April 5, contained some forcible truths, which the profession would do well to ponder. We have a few words to say at present in support and in extension of our correspondent's views.

He is perfectly right in stating that a great many persons become beneficiaries of charitable institutions who are well able to pay for medical advice. For the last twenty years we have observed this evil steadily growing, with the increase in the number of these establishments. As a matter of course, this is the case with the dispensaries from which the college clinics are fed; for all who come there must be attended to, so as to accumulate material from which to cull what is suitable for exhibition before a class. These, however, are not charities in any strict sense of the term; they are only such incidentally, and for a purpose.

But there is between institutions of the purely charitable class a certain rivalry, not as to the amount of actual good done to the deserving poor, but as to the number of cases attended, the number and brilliancy of operations performed, etc. An "interesting case" is too often admitted on the free list, to the exclusion of one of real suffering and destitution which presents no chance for trying some new method, or for great surgical exploits. This is all wrong. The generous offerings of the public should be applied to the relief of poverty and distress; and those patients who can pay for attendance should be required to do so.

Again, there are many private practitioners who give their services to those who are well able to pay, and who would do so if they were rightly dealt with. We allude to servant-girls, mechanics, and others in the lower ranks of life. These people indulge in many luxuries of dress and amusement, but expect to have what medical attendance they need either gratis or for a nominal sum.

Another point we touch upon with some apprehension lest we should be misunderstood. The relation between physicians and the clergy has never been clearly established. There is a generally prevalent idea that medical services are to be rendered gratuitously, as of right, to members of the latter profession. And yet it is among clergymen that quacks and quack medicines have ever found ready and willing patrons and endorsers. In large cities, at least, the pecuniary position of the clergy as a class is more comfortable than that of physicians as a class. And we cannot but think that they ought to decline to lie under obligation to a body of men so largely drawn upon for charity as medical men are.

All these things would be, in our humble opinion, rectified by a little common sense, thoroughly carried out. Let every physician, whether in a public capacity or in his private practice, look upon his services as having a definite marketable value. Let him consider that those who seek his services ought, if they can, to pay for them, and if they cannot, to receive them as charity. He may, if he sees proper, decline to charge his clergyman, or any other friend, for services rendered; but no one can claim medical advice from him, any more than he himself can demand tea or coffee from a grocer, or meat from a butcher, without offering a due equivalent.

A DIFFERENT THING.

OUR esteemed cotemporary, the *Boston Medical and Surgical Journal*, in its issue of April 10, has the following item:

"NOT AMERICAN THIS TIME!—'It has just come to light,' says the *Lancet* of March 22, 1873, 'that during the last few years a large trade has been going on in forged diplomas purporting to be from the *German* University of Marburg, no less than forty persons in this country having purchased the worthless documents.'"

This, we submit, is quite a different thing from the "American" business of diploma-selling, which

we and others have sought to destroy. Its effects, indeed, are the same, in that unqualified persons are furnished with the means of imposing on the public. But it is a mere matter of forgery: the genuine diplomas of the University of Marburg, a highly respectable institution, are imitated.

Obviously, in this case the makers and sellers of the spurious diplomas on the one hand, and the buyers and users on the other, are the guilty parties. The injury falls on the University, whose genuine certificates must depreciate in value, and on the public, who are led by the false papers to repose confidence in their holders.

Far otherwise was it in the case of the bogus colleges in this State. Here the authority of the legislature was invoked to establish and to sanction institutions which, for a mere pecuniary consideration, issued diplomas which, though genuine, were valueless. Every medical school in Pennsylvania, and in fact in the United States, has suffered in standing, every "American diploma" has become a thing of uncertainty, open to more or less suspicion; and yet the evil has been far more difficult to deal with, and has not yet been wholly reached.

SOME SANITARY FACTS.

WE would call attention to a few curious facts, which are perhaps susceptible of some explanation which has not, as yet, occurred to us, in regard to the mortality of this city.

Notwithstanding the severity of the winter, the death-rate has been uniformly and markedly lower, week by week, than during the corresponding months of 1871–2; and this in a degree, it seems to us, much greater than can be accounted for by the variolous epidemic of the winter before last.

Again, while the interments for the week ending April 5 were 332, the number fell to 256 for the ensuing seven days. The deaths from consumption, in the latter period, were but 28 to 63 in the former; a diminution of over 50 per cent. The deaths from other diseases of the respiratory organs fell from 48 to 33; a diminution of nearly 32 per cent.

Another point which strikes us as singular, although it may be that it is the rule in other cities also, is the large number of deaths ascribed to diseases of the brain and nervous system. The average for thirty consecutive weeks was 46; the smallest number having been for the week ending October 19, 1872,—30, and the largest for the week ending March 15, 1873,—71.

These facts have happened to attract our notice casually, and are perhaps by no means the most remarkable of those which a closer study of our vital statistics would develop. We should be very glad to think that the whole subject was under careful investigation here, and that the result might be of benefit to the public welfare.

CORRECTION.

IN the report of Prof. Gross's clinical lecture on lithotomy (page 420 of this volume) the following corrections made in the proof arrived too late to be made in the published report: When sounding the patient, instead of "perfectly nude," read "the lower part of the body should be nude;" and, for "the bladder should be full of urine," read "it should contain three or four ounces of fluid."

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, March 26, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

DR. CHARLES S. HOYT, Secretary of the Board of Public Charities of the State of New York, spoke on the subject of the *care of the insane*, and remarked that the census report had not been reliable as to the number of insane people in the country, which had been shown by the census of insane taken in two or three instances by boards of public charities.

It was found in 1871 by Dr. Hoyt that the total number of insane in this State was 6775. Of these, 1582 were in the custody of friends, 1093 in State institutions, 312 in private institutions, 3552 in city and county poor-houses, and 161 in institutions in other States. In Albany County the number of insane is 223, or 1 to 551 inhabitants,—a larger proportion than any other county, except Oneida, New York, and Kings. Of these, 66 are in the county poor-house and 105 in State institutions, the rest being scattered in private institutions, taken to other States, or retained in the custody of friends.

It has been a matter of interest to find how many have become insane during the year. There have been 761 recoveries and 502 deaths among the insane of the State. By deducting from the total number of insane it is found that 1678 new cases of insanity have occurred, or 1 to every 2612 of population.

The circumstances under which the insane have recovered are largely in favor of hospital treatment. Of 761 recoveries only 43 were of those under the care of friends. It was urged on physicians to send insane patients as soon as possible to the asylum, and also to try and remove the prejudice existing against these institutions, which is largely due to lack of information.

The charges that have been made from time to time are for the most part unfounded. Those against Bloomingdale are shown to have been entirely malicious. The

hope of recovery diminishes as time advances,—a large proportion of recoveries being within a year.

It was urged that this county could best take care of its insane by building an asylum of its own, and that this would be more economical. It costs from $20 to $35 to transport patients to distant institutions, which sum would pay the interest on the cost of building.

There are now 66 insane in the county poor-house because of lack of accommodations elsewhere; and they ought not to be deprived of advantages which the others enjoy. Epileptics, too, are a dangerous class to have at large, and for them there is no public provision. He thought that the cost of maintaining 250 patients would be about three dollars a week, in an institution having a large vegetable farm attached. This is what is paid by the county for patients at the Willard Asylum. Mr. Hoxsie—overseer of the poor of the County of Albany—said that we have 102 patients in the Willard Asylum, and 50 or 60 whom he would be glad to send there if there was room. A number of supposed hopelessly insane sent to Willard Asylum, when first established, had been returned cured. He spoke highly of the care given there. The supervisors of this county decided not to build an asylum, on account of the expense, but they had appropriated $35,000 for this year's care, the largest ever set apart. We shall never have a less number; and it would not take many sums of this amount to erect a home asylum. It might, too, be made remunerative by taking from other counties. The accommodations in the State asylums are entirely insufficient, as shown by the fact that they are crowded, and many patients are now in other States or in the custody of friends.

Dr. James S. Bailey reported a case of *poisoning by aniline*. A workman in the employ of the Aniline Company undertook, contrary to the advice of the foreman, to open an iron cask containing aniline oil and arsenious acid. The gas formed by the intense summer heat was liberated, and, being inhaled, caused asphyxia. He was carried home in an insensible condition, and remained so for fourteen hours, and he was prostrated for two weeks by a bronchial affection caused by the irritation which the gas produced in the air-passages.

In 1868, Professor Wirtz, of Paris, while demonstrating the properties of aniline as a coloring-matter before his class, applied heat, and on inhaling the fumes fell senseless, and immediately expired.

Dr. James S. Bailey also reported the history and post-mortem appearances of a case of *rupture of the œsophagus* occurring near the cardiac orifice of the stomach, causing collapse and death in twenty-four hours from its occurrence. In this case the accident was probably due to a violent fit of vomiting. Substances swallowed passed into the cavity of the chest through the fissure.

The lesion in a sound œsophagus is a rare one. Von Oppolzer reports having seen but one case.

Dr. Albert Van Derveer reported the following interesting case of *pyelitis*.

Mr. C., æt. 45; sailor; exposed to great hardships from boyhood. Complained of nausea and vomiting, and pain in lumbar region; difficulty in urinating, and a frequent desire to do so night and day, but passing but little at a time. Respiration was frequent and labored.

Examination of urine revealed one-third albumen, with an abundance of pus-corpuscles.

Post-mortem made five hours after death, in order to enable the friends to transport the body a distance for burial. Body much emaciated. There were strong pleuritic adhesions extending over the entire surface of both lungs, evidently of long standing. Lung-tissue healthy. Heart normal. Liver somewhat enlarged, pale, and fatty. When the peritoneal coat is torn off, portions of the liver follow, giving it a granular look; the tissue is easily torn. Spleen and pancreas, stomach and intestines, normal.

Kidneys.—Right one firmly held in lumbar region by adhesive inflammation of surrounding cellular tissue; with difficulty removed; appears large, full, and distinctly fluctuating. Ureters very much enlarged and thickened; upon section a pus-like fluid freely escapes. The kidney measures six inches in length, four inches in width, and three inches in thickness, and weighs twelve ounces. No fat or tissues left attached to capsule; capsule firmly adherent to the small portion left of the cortical substance. The tubular part seemed completely occupied by from twelve to fifteen distinct abscesses, and these seem to have destroyed particularly the pyramids, occupying their places. There is a well-defined wall existing between most of the abscesses, all of which have their exit towards the pelvis of the kidney. Not a well-defined pyramid is left, and but a small portion of the cortical substance remains. Left kidney easily removed; large and of a pale color; two or three small cysts on its surface; weight seven ounces, length six and a quarter inches, width three and a half inches, thickness two inches. Capsule easily removed; cortical surface appearing coarse and granular. Upon laying open the organ, the pyramids were well defined, but appear coarse and congested; the cortical substance also appears congested.

Microscopical appearances of the left kidney, by Dr. Blatner.—The consistence of kidney is soft, and paler in color than normal. The contrast between the cortical and medullary substance is striking. There is a diffuse cellular hyperplasia of the connective tissue near the convoluted urinary tubuli and the Malpighian corpuscles. There are also numberless young cells and some oil-globules perceptible. The Malpighian corpuscles have also become shrivelled.

REVIEWS AND BOOK NOTICES.

Diseases of the Urinary Organs: including Stricture of the Urethra, Affections of the Prostate, and Stone in the Bladder. By John W. S. Gouley, M.D., etc., etc. With One Hundred and Three Wood Engravings. 8vo, pp. 368. New York, William Wood & Company, 1873.

The title of this work is too comprehensive, since it would lead any one to suppose that the diseases of the kidneys are discussed in it, whereas it embraces but a limited number of the vesical and urethral troubles of the male sex only. And it is devoted almost exclusively to the surgical treatment of this class of disorders. A better name would have been "Vesical and Urethral Surgery."

Dr. Gouley has written clearly and well, from a large practical experience; and we have little to say except in commendation of his work. He begins with a tolerably full résumé of facts in regard to stricture of the urethra, its causes, symptoms, and sequelæ. For the diagnosis of this troublesome affection he justly prefers the bulbous or olivary bougie.

We are somewhat surprised at the way in which the endoscope is mentioned, since the reader is not informed as to the extent to which it is used or the value of its revelations. Unless we are much mistaken, this instrument has altogether disappointed the expectations of its friends, and has been laid aside even by those who a few years ago were warmest in its praise.

Dr. Gouley is well known as one of the advocates of "tunnelled" instruments for stricture; and he gives very full directions for this plan, which we believe to have great merits. The idea is to employ a fine whale-

bone guide, which, being carried past the seat of constriction, may serve to lead a metallic instrument, grooved or tunnelled so as to slide along into the bladder. Whether for dilatation, divulsion, external or internal urethrotomy, this method has, in our author's hands, been found practically valuable. All the disorders causing difficulty in urination are quite fully discussed, with the various modes of treating them.

The concluding portion of the book, on stone in the bladder, occupies three chapters. Lithotripsy, lithotomy, and perineal lithotrity after the method of Dolbeau, are well described and fully illustrated. Our author gives a very decided opinion, backed by a larger array of statistics than we had supposed available, in favor of median lithotomy.

We are very glad to welcome this able contribution to American surgical literature. It is not so exhaustive as the treatises of Sir Henry Thompson on Stricture and on Lithotrity and Lithotomy, nor does it pretend to be; but it is a very clearly-written and practical guide, and will be found useful by a large class of readers. Its mechanical execution is very creditable, and it contains remarkably few typographical errors.

THE SCIENCE AND ART OF SURGERY: being a Treatise on Surgical Injuries, Diseases, and Operations. By JOHN ERIC ERICHSEN, Senior Surgeon to University College Hospital, etc. A New Edition, enlarged and carefully revised by the Author. Illustrated by upwards of Seven Hundred Engravings on Wood. 2 vols. 8vo, pp. 781–918. Philadelphia, Henry C. Lea, 1873.

Mr. Erichsen's work, which has now attained a size which necessitates two volumes even for the American edition,—and they are much pleasanter to handle than their enormous single predecessor,—is unmistakably a London book, by a London author, and suited, we may say, to London readers. That it is valuable would be evident merely from the demand which warrants a sixth re-issue of it, despite its many younger and fresher rivals for the favor of the profession. And yet it has never been a very satisfactory book to us, from the diffuseness of its style, and the scanty references given, but above all for a certain lack of spirit.

The author takes up his subjects, discusses them, and lays them down, one after another, with propriety and correctness, but without enthusiasm. He seems to place a good deal of stress upon matters which are not, after all, the essence of surgery,—rather preferring complicated forms of apparatus and procedures which require special appliances. Hence his book would fail to meet the needs of some of our brethren who are out of the way of instrument-makers, and must achieve their triumphs—and noble triumphs they often are—by working out principles with rough and ready tools.

We note that in the present edition the modern researches in pathology, by Cohnheim and others, are mentioned; and the valuable contribution of Dr. Bigelow to the surgery of the hip-joint receives due weight. Lister's antiseptic method is described with approbation. Chloroform seems to be the anæsthetic decidedly preferred, notwithstanding its risks.

Mr. Erichsen does not appear to have adopted the modern views in regard to syphilis. His chapter on venereal diseases is, indeed, the least satisfactory in the book. He thinks that some mercurial treatment is almost always required,—an opinion which we hardly think has many adherents in this country at the present day.

The illustrations which have been added in this edition are very inferior, not only artistically, but as aids to the understanding of the text. For example, the cut on page 488 of vol. ii., of a laryngoscopic examination, is incorrect in almost every particular.

We have found much fault, but honestly, with this work. We do not think it can be accepted as a cyclopedia of surgery. And yet it is a book which every surgeon who has a library will do well to buy and to consult, as containing, in spite of its defects, the results of the experience in hospital and private practice of one of the leading men of the day.

TEXT-BOOK OF PHYSIOLOGY: General, Special, and Practical. By JOHN HUGHES BENNETT, M.D., F.R.S.E., Professor of the Institutes of Medicine or Physiology, and Senior Professor of Clinical Medicine, in the University of Edinburgh, etc., etc. With twenty-one Photo-lithographic Plates. Small 8vo, pp. 606. Philadelphia, J. B. Lippincott & Co., 1873.

This may fairly be placed in the rank of "great little books." It is written in a singularly clear and concise style, with no waste of words, and yet is pleasantly readable. A somewhat careful examination of it has satisfied us that it is fully up to the present state of science, and well adapted to the wants of the student, as well as of the more advanced reader.

The work is divided into three parts. Part I., on General Physiology, embraces the Chemistry of the Tissues, General Histology, the Physical and Vital Properties of the Tissues, and Life or Vitality. In Part II., on Special Physiology, are treated Nutrition, Innervation, Reproduction, and Death. Part III., on Practical Physiology, is devoted to Practical Chemical Physiology, Practical Histological Physiology, and Practical Experimental Physiology.

The illustrations, which are on a somewhat small scale, are very good. They are massed together at the end of the volume, with explanatory pages opposite to each plate. This arrangement, as well as the photo-lithographic method, was adopted for the sake of economy, and, we think, wisely.

We regret to note a good many typographical errors; but none are of serious moment. We regret also that so few Americans have given themselves to researches in this branch of science, so that hardly a single countryman of ours is to be found among the many authorities quoted.

MYRINGECTOMY, ETC. By J. S. PROUT, M.D., of Brooklyn, N.Y.

This is an account of a case of chronic catarrh of the middle ear, in a lady, thirty-three years old, relieved by myringectomy, after all other remedial measures had failed. The hearing-power for the watch and voice steadily decreased, although the catarrhal condition of the throat and Eustachian tubes was relieved. At last, an adhesion between the membrana tympani and the promontory was discovered, which we are left to infer occurred during the treatment. Its presence was indubitably settled by the use of Siegle's pneumatic aural speculum. The operation was performed upon the right ear, but produced no improvement in the hearing-power for the watch,—normally audible thirty-six inches,—although immediately after the operation the *voice* in conversation was heard very much better. But the voice is such a treacherous test!

The author explains the improvement in hearing in the following words:

"The membrane of the round window now receives the sound-waves and transmits them to the auditory nerve in the cochlea.

"Some of the improvement may be perhaps attributed to an improved co-ordination in the vibrating power. The two membranes may have been unequally attuned, and, therefore, a condition somewhat similar to diplopia may have existed. There was no double hearing."

One year after the operation the opening in the membrana tympani had not closed,—a fact which the author does not attempt to explain.

It is to this permanent opening we may ascribe the improvement in hearing,—in this case as well as in others where the opening has been maintained.

C. H. B.

THE CREDIT GUIDE. Philadelphia. Vol. II., No. 1, 1873, pp. 144.

This is a book the merits of which can scarcely be recognized by casual examination. We have reason to know that the compilers have endeavored to make it as full and as correct as possible; and it would be well for the practitioners of the city to give a fair trial to this attempt to furnish a defence against those who are willing to evade payment of their bills. Copies may be obtained by addressing the agent, Mr. R. A. Schwab, No. 711 North Twentieth Street.

GLEANINGS FROM OUR EXCHANGES.

PODOLINSKI ON THE EXPULSION OF CARBONIC OXIDE AND NITRIC OXIDE FROM THE BLOOD.—In opposition to commonly received opinions, Donders recently stated that carbonic oxide could be expelled from its hæmoglobin compound by other gases; and Zuntz has separated it by means of the vacuum. S. Podolinski (Pflüger's *Archiv*, vol. vi., part 11), under the direction of Hermann, compares the comparative displacing power of hydrogen and oxygen on the carbonic oxide compound, and also on the nitric oxide compound with hæmoglobin. He finds, on operating on small quantities of carbonic oxide blood with hydrogen, in a manner which allows complete mixture of the two, that half an hour is sufficient to expel all the carbonic oxide from blood saturated with this gas. Atmospheric air acts still more rapidly. In regard to nitric oxide in blood, hydrogen alone was used to expel the gas, in order to avoid formation of nitric peroxide. In this case, also, the compound was completely broken up, and nitric oxide expelled, but longer time was necessary. Hence Donders's discovery that carbonic oxide can be expelled by indifferent gases is extended to nitric oxide; and therefore the relation of hæmoglobin to the gases combining with it is, that oxygen, carbonic oxide, and nitric oxide can be expelled by indifferent gases, the degree of difficulty increasing in the same order. Each of these gases can be expelled by the one immediately following it with more ease than by an indifferent gas, and apparently, also, each is more easily evolved by the action of the one immediately preceding.

EMETICS AND NAUSEANTS.—*Le Mouvement Médicale* quotes from the *Bulletin de Thérapeutique* of March 15 the following remarks, from an article, by M. D'Ornellas, on the physiology of vomiting:

"The distinction between emetics pure and nauseant emetics is not altogether natural, since characteristic examples of each variety are rare, and the two effects are generally found combined in the same substance. M. Gubler thinks that an emetic is energetic in proportion to its nauseousness, acting not only on the stomach, but also on the buccal, nasal, and pharyngeal cavities. There is no doubt that the direct action of some articles is due to a different substance from that which produces the indirect. Thus the nauseant action of ipecacuanha is due to a principle having odor, and separable by ether (Magendie and Pelletier), the emetic influence to emetia, separable by water, and especially by alcohol (Magendie). These substances act as follows: The emetia acts always directly upon the gastric mucous membrane, upon its sensitive nerves, while, on the other hand, the nauseant principle acts upon the nerves of special sense, of the tongue, pharynx, and nose, and causes vomiting as soon as it is swallowed, or even before, independently of any local gastric action, or of elimination."

CONGENITAL ABSENCE OF A PORTION OF THE PECTORALIS MAJOR MUSCLE, AND THE WHOLE OF THE PECTORALIS MINOR ON THE LEFT SIDE (*Lancet*, March 15).—Dr. Burney Yeo reported this case at a recent meeting of the Clinical Society of London, and exhibited the patient, a boy aged 14. The case had come under his notice as an out-patient at the Brompton Hospital, the great apparent depression and flattening of the right side of the chest having induced the boy's friends to believe that he was suffering from serious intra-thoracic disease. The deformity produced by the absence of these muscles was very considerable, and was increased by depression and imperfect development of the right side of the sternum and the adjacent ribs and cartilages. No ensiform appendage could be felt. The clavicular portion of the pectoralis major was considerably hypertrophied, and the posterior fold of the axilla, containing the fibres of the latissimus dorsi, felt much thicker than that on the opposite side. There was a remarkable difference in the radial pulses on the two sides,—that on the right side being exceedingly small and weak, seeming to indicate some irregular distribution of the vessels on the same side as the muscular abnormality. The boy in all other respects was well developed, though small. He had never complained of any weakness of the right arm, and he was not left-handed. Dr. Yeo believed that a similar muscular defect had been rarely observed during life. He had appealed to Professors Flower, Humphry, and John Wood, and they had all assured him that they had heard of no like observations in the living subject. Several anatomists had recorded partial absence of the pectoral muscles observed on dissection, and within the last few days Mr. Taylor, of Guildford, had informed Dr. Yeo that he had now under his observation a volunteer in the Second Surrey Militia, with complete absence of the left pectoralis major. Cyrtometric tracings, showing the difference in the dimensions of the two sides of the chest, were handed round.

Mr. Nunn showed a sketch of a similar case, in which also some deficiency in the latissimus dorsi existed, and remarked that another case of a similar kind had come under his notice, having been treated previously at a special hospital for deformities, the authorities at which had enjoined the use of a back-board.

Another case of this anomaly is put on record by a correspondent of the *Lancet* for March 29, as follows:

"Four years ago, in India, while at the house of a cavalry officer, a quondam medical student, he took the opportunity of exhibiting this freak of nature. He was a man of powerful build, and excelled at all athletic sports. There seemed a great triangular depression on the right side of the thorax; but it was at once seen that this was not due to any falling in of the ribs. The well-developed left breast, and the large rounded right shoulder, rendered the absence of the muscle extremely well marked, especially at the acromial end of the clavicle, where there was a very well-defined hollow."

THE TRANSFUSION OF BLOOD.—The Transfusion Committee, appointed by the Obstetrical Society of London, has adopted the following programme of its aims and objects:

1. To collect evidence from gentlemen who have had experience in cases of transfusion.

2. To obtain the particulars of all recorded cases (performed on the human subject), with the view of finding out, as far as possible, to what extent the so-called successful cases were due to transfusion.

3. To examine the various kinds of instruments used in both the mediate and immediate forms of the operation.

4. If considered necessary, to institute further experiments for the purpose of determining how far transfusion may be relied upon as a means of saving life, and also the best mode of performing the operation.

Sirédey and Cordier on the Treatment of Anasarca, Ascites, and Obstinate Pleuritic Effusions by Milk.—MM. Sirédey and Cordier (*Journal de Médecine et de Chirurgie Pratiques*) have used this old and rather favorite remedy against dropsies in a way which they consider renders it less troublesome and repugnant than the "milk-cure" is otherwise apt to be. At the same time that Sirédey prescribes two pints of milk a day to his patients, he allows other kinds of food and drink. Cordier, in his thesis, cites cases of albuminuric dropsy in which the diuresis was rapid and considerable, and the dropsy disappeared under this treatment. The diet is otherwise moderate, including meat and a little wine. He does not give more than two to two and a half pints of milk, at convenient intervals, in the day. He prefers asses' milk.

Isnard on the Treatment of Constipation by Arsenic.—Dr. Isnard (*Marseille Médical*, 1872) states that many other physicians besides himself have observed that arsenic excites the appetite and improves the digestion, and facilitates the action of the bowels, but he is not aware that it has been methodically applied for the relief of constipation. Besides (1) improving the appetite, it (2) excites the muscular action of the intestines, and (3) it augments the secretions of the alimentary mucous membrane. It is particularly useful in the constipation of debilitated and anæmic females, sedentary persons, and old people. He administers arsenious acid in the dose of six to ten milligrammes, twice or thrice a day, with food. Sometimes smaller doses suffice. It may be used steadily for some time.

Digitalis an Anaphrodisiac.—M. Gourvat, in the course of a paper published in the *Gazette Médicale de Paris*, on the action of digitalis, says, "When digitalis or digitalin is administered for some time to a man in full possession of sexual powers, these become gradually weakened, the propensities disappear, formation of the liquor seminis diminishes, and may at last cease altogether. The anaphrodisiac properties of the drug are the secret of its good effect in spermatorrhœa."

MISCELLANY.

The British Death-Rate.—The London *Echo* quotes as follows from official statements: "Taking an average for the thirty-three years, 1838–70, we find that the number of deaths in England to every 1000 of the population is 22.4. Of course, the death-rate varies with each year, the figures ranging from 20.5 in 1856 to 25.1 in 1849, when the cholera visited us with fearful severity, destroying no fewer than 53,273 lives,—13,161 in London alone, and in little more than three months. The twelve most fatal causes are as follow, the figures attached showing the number of deaths due to each disease in 1870: phthisis (consumption), 54,231; bronchitis, 46,699; scarlet fever, 32,543; atrophy and debility, 30,530; old age, 28,889; convulsions, 26,548; diarrhœa, 25,311; heart-disease, 23,957; pneumonia, 23,729; hooping-cough, 11,901; paralysis, 11,651; and apoplexy, 11,598.

"From alcoholic poisoning 645 deaths resulted, 337 being cases of delirium tremens. Heart-disease seems to be on the increase, which is attributed by eminent physicians to the greater wear and tear of business and the increased mental activity of the age. To external causes 16,593 deaths in the year were directly referred. By railway-accidents 930 persons lost their lives; by accidents in coal-mines, 1000; 'mechanical injuries' killed 5730,—4136 arising out of 'horse-conveyance,' and 454 from the fall of heavy substances. Sunstroke killed 112 persons, and lightning 19. Of deaths by suffocation, 444 young children were smothered by bedclothes, and 171 were 'overlaid.' The proportion of suicides to every million of the population is about 70; the deaths by hanging, the knife, and drowning, being most numerous."

Here is a nut for honest homœopathists to crack. The *Homœopathic Review* says,—

"The obligations of the homœopathic practitioner to his patients to relieve pain and to stave off death are higher than his duty to practise homœopathy. If he cannot, whether from the incompleteness of science, or from his own imperfect acquaintance with it, prescribe homœopathically, he must use such measures as, within his knowledge, are most likely to achieve the end he has in view. He is the most successful physician who, within the limits where a homœopathically acting medicine can effect good, can relieve and cure, *most seldom* falls back upon an allopathic palliative."

The plain English of this is, that the dogma "*similia similibus curantur*," with the psoric theory of chronic disease, the attenuations, potencies, triturations, and dilutions of medicines, will not hold water, and must be abandoned when matters begin to look serious.

International Medical Congress in Vienna.—The third international medical congress will be held in Vienna during the week from September 24 to October 1, under the patronage of the Archduke Rainer. The following are the subjects proposed by the Executive Committee for discussion: 1. Vaccination; 2. Quarantine in its Relation to Cholera; 3. Prostitution; 4. The Sanitation of Towns; 5. Proposals for an International Pharmacopœia; 6. Proposals for making Medical Education as uniform as possible in all countries, and for establishing reciprocal right of practice. The German language will be used in introducing the subjects; but the subsequent discussions may be in French, English, or Italian, as well as in German.

Richard Partridge, F.R.S., a well-known surgeon and anatomist of London, Professor of Anatomy for twenty years to the Royal Academy of Arts, and for thirty-six years to King's College Hospital, died recently, aged 68. He was one of the surgeons summoned to attend Garibaldi after the battle of Aspromonte, but failed to find the ball which Nélaton afterwards detected with his porcelain-tipped probe.

Medical Advertising.—The Council of the Royal College of Surgeons has, upon the motion of Mr. Charles Hawkins, passed the following resolution:

"That the practice of frequently advertising medical works in the non-medical press is, in the opinion of the Council of the Royal College of Surgeons of England, not conducive to the honor and dignity of the medical profession."

An editor says, "We have lately heard of the diagnosis of a new disease discovered by our associate editor, Dr. S., not long since. A lady of remarkable conversational powers approached our medical friend with, 'Dr. S., I have a very sore tongue.' 'Let me look at it,' says the doctor. The unruly member was duly protruded. 'It is sunburnt, madam, sunburnt,' remarked the doctor, who suddenly recollected that his professional services were wanted in another direction."

The out-door physicians of the Guardians of the Poor have formed themselves into an association, with the following gentlemen as officers:

President, M. B. Musser, M.D.
Vice-President, E. J. Nolan, M.D.
Secretary, A. C. W. Beecher, M.D.
Treasurer, Frank B. Hazel, M.D.

Asylum Amenities.—"Injuries inflicted upon patients in insane hospitals are generally the result of an inadequate number of servants in immediate attendance on the inmates. With a sufficient number of attendants always present, the most perverse patient, perceiving non-compliance utterly useless, will quietly submit." Such was Conolly's advice thirty years ago.

According to the *Lancet*, the Registrar-General states, in his annual summary of the weekly returns, that London has now upwards of four million souls, and had in the middle of 1872, within the limits of the health returns, 3,311,298 inhabitants. The estimated increase of population was 44,839. The average mortality of the year was 21 per 1000.

American Medical Association.—The undersigned proposes to charter a *palace car* for the trip to St. Louis. Cost to each passenger, six dollars. Leave Philadelphia May 2, noon; Baltimore, 4.15 P.M. All who desire to avail themselves of this opportunity should address

W. B. Atkinson,
1400 Pine Street.

At a recent meeting of the Société de Biologie, in Paris, M. Cl. Bernard announced that the daughter of the late M. Rayer had sent a donation of six hundred francs, in token of the interest taken by her father in the society. The money would be applied to the publication of the proceedings.

Philadelphia County Medical Society.—Dr. J. Solis Cohen will deliver a lecture at the Conversational Meeting, April 23, at 8 P.M., on Acoustic Phenomena, Normal and Pathological, illustrated by physical and physiological experiments.

The treasurer of the Aberdeen Infirmary, in a letter to *The Times*, asserts that "Hospital Sunday" has been an institution in that city since 1784.

Mortality of Philadelphia.—The interments reported at the Health Office for the week ending April 12, 1873, were 256; 138 adults, and 118 minors. 10 were of bodies brought from the country; making the mortality of the city 246. Among the assigned causes of death were:

Consumption of the Lungs	28
Other Diseases of the Respiratory Organs	33
Diseases of the Circulatory Apparatus	11
Diseases of the Brain and Nervous System	54
Diseases of the Digestive Apparatus	24
Zymotic Diseases	25
Typhoid Fever	3
Diseases of the Urinary Organs	5
Casualties	8
Cancer	9
Debility (including "Inanition" and "Marasmus")	24
Still-born	13
Old Age	7

(The interments reported for the week ending April 13, 1872, were 439.)

The meteorological record kept at the Pennsylvania Hospital was as follows:

		THERMOMETER.		BAROMETER. (2 P.M.)
		Max.	Min.	
April	6	60.0°	42.0°	30.15 in. (Thunder-storm.)
"	7	61.0	44.5	30.09 in.
"	8	62.0	47.0	29.95 in.
"	9	57.0	51.5	30.02 in. (Thunder-storm.)
"	10	59.0	45.5	30.28 in.
"	11	69.5	47.0	30.20 in.
"	12	43.5	36.5	29.83 in. (Rain and Snow.)

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 8, 1873, TO APRIL 14, 1873, INCLUSIVE.

White, Robert H., Assistant-Surgeon.—Relieved from duty in the Department of the South, and to report to the Commanding General Department of the Lakes for assignment to duty. S. O. 74, A. G. O., April 9, 1873.

Kimball, J. P., Assistant-Surgeon.—To proceed to Yankton, D.T., and report to the Commanding Officer Battalion 7th Cavalry, for duty upon the Yellowstone Expedition. S. O. 64, Department of Dakota, April 2, 1873.

Carson, Joseph K., Assistant-Surgeon.—To report in person to the Commanding General Department of the South, for assignment to duty. S. O. 74, c. s., A. G. O.

Matthews, W., Assistant-Surgeon.—Relieved from duty at Willett's Point, N. Y. H., and to report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 78, A. G. O., April 12, 1873.

McMillin, Thomas, Assistant-Surgeon.—Died, April 6, 1873, in camp at Headquarters Modoc Expedition.

Transactions of the Third Annual Session of the Medical Society of Virginia, 1872. 8vo, pp. 178.

SATURDAY, APRIL 26, 1873.

ORIGINAL LECTURES.

LECTURES

ON THE SURGERY OF THE NARES, LARYNX, AND TRACHEA.

BEING THE MÜTTER LECTURES FOR 1872.

Delivered before the College of Physicians of Philadelphia,

BY J. SOLIS COHEN, M.D.

Reported by R. M. BERTOLET, M.D.

(Continued from page 452.)

LECTURE IX.

INFLAMMATORY AFFECTIONS OF THE NASAL PASSAGES.

NASAL ABSCESS.

ABSCESS of the nasal passages is met with in the inflammation resulting from traumatic injury, in that of common chronic coryza, and in that of syphilis, and occasionally in idiopathic inflammation, the result of sudden exposure to change of temperature, or that condition of system which gives rise to the formation of boils. Such abscesses are developed in the sub-mucous connective tissue, usually not far from the exterior orifice, and may occupy the septum or ala. They may be small, like a little boil, or large enough to occlude the affected nostril and press the septum aside. Sometimes the exterior of the nose is swollen, and also more or less of the face, even, in some instances, to the production of œdema. The phenomena of fever are present in severe cases.

Left to itself, the abscess ruptures spontaneously in a few days; but the duration of the affection can be lessened by opening the abscess with the knife. If the inflammation is severe, a leech may be applied within the nostril. Warm-water applications are very beneficial, impregnated with sedatives or astringents.

Syphilitic abscess is usually a tertiary manifestation originating by a gummous deposit. Its progress is slower than that of acute abscess; it is less painful, and attended by a less viscid discharge. After rupture of the abscess, the discharge is thicker, purulent, sanious, and offensive. Perforation of the septum is not an infrequent result. The local treatment is the same as for ordinary abscess, in the first instance; but the resulting ulcer may require the local application of nitrate of mercury and the like. The patient should be brought under the systemic influence of iodide of potassium.

Guersant speaks of having frequently encountered nasal abscess in infants supposed to be affected with polypi. He attributes the affection usually to blows and falls, but has seen it dependent on caries and necrosis of the vomer, etc.

Chronic inflammation, especially when syphilitic or scrofulous, frequently terminates in ulcerative destruction of more or less of the cartilaginous septum; occasionally by one large orifice, sometimes by several small perforations. The edges of the perforations require frequent cleansing, and occasional touching with caustics. Operations for closure of large perforations have been performed by plastic transplantation of mucous membrane.

CORYZA.

Coryza is an acute catarrhal inflammation of the nasal mucous membrane, sometimes confined to one nostril, but more frequently affecting both, and often extending into the maxillary sinus, frontal sinus, lachrymal duct, and Eustachian tube. The mucous membrane is red and swollen, and discharges a more or less copious secretion, which varies in quality at different stages of the affection; being at first serous, then sero-purulent, and loaded with salines, which sometimes excoriate the tissues. Sometimes fibrin is secreted, and collects in a membranous layer.

The symptoms of this affection are too well known to need enumeration; when severe, pain will be felt in all the localities implicated in the inflammation, and there will be headache, insomnia, loss of appetite, and general languor. Nasal respiration will be more or less obstructed, until a copious discharge takes place which relieves the distended tissues. The affection subsides spontaneously in a few days, rarely progressing to suppuration. Sometimes a series of attacks follow in a more or less rapid succession.

A peculiar syphilitic coryza is noticed in children, due usually to the development of mucous patches, often progressing to ulceration, with more or less destruction of cartilage and bone.

Coryza can often be broken up by inducing copious diaphoresis within the first twelve or twenty-four hours of the attack. The snuffing up of vapors of iodine, camphor, chloride of ammonium, or other substances, sometimes accelerates the stages of the affection and brings it to a prompt conclusion in a few hours. When fully established, the suffering can be lessened by warm foot-baths, warm aromatic drinks, and the use of anodynes to promote sleep.

An idiosyncratic inflammation of the nasal passages and parts adjacent occurs in certain individuals from the inhalation of various vegetable and animal emanations that periodically appear in the atmosphere. The distress is very severe, and the usual symptoms are those of ordinary coryza. Change of locality at the usual time of the attack is often the only remedy, care being taken to seek a residence where the special conditions productive of the affection are not present. In some instances quinia or carbolic acid, injected into the nostrils, seems to destroy the organisms which produce the disease.

CHRONIC CORYZA.

Chronic inflammation of the nasal passages may be catarrhal, scrofulous, or syphilitic. It usually produces a more or less hypertrophied, and sometimes an indurated, condition of the mucous mem-

brane of the turbinated bones and of the alæ of the nostrils. Sometimes the hypertrophied membrane protrudes into the passage, so as to be mistaken for fibroid formations. Small polypi and warty excrescences are not infrequently developed in addition.

The inflammation of simple catarrhal chronic coryza rarely leads to ulceration; but that of scrofula and syphilis is quite prone to ulcerate. In addition to this, specific inflammation not infrequently destroys more or less of the cartilaginous and bony structures, giving rise to an offensive discharge, which is characterized by the term ozæna.

The products of secretion are not discharged freely, portions of them remaining pent up in the sinuosities of the passages, where they undergo decomposition. They are discharged in crusts or lumps at irregular intervals.

The symptoms of the affection are: more or less obstruction to nasal inspiration, and the presence of morbid discharges from the nostrils and from the posterior nares.

The treatment of the affection consists principally in the prompt removal of the accumulated products of secretion, and the maintenance of the general vigor, by proper diet, exercise, and cleanliness of habit. The parts should be syringed or washed out by the nasal douche several times a day, water in liberal quantities being used for the purpose, impregnated with salt, bicarbonate of soda, chlorate of potassium, and the like, to assist in the detachment of adherent inspissated mucus and pus. The water used should be warm. After the parts are cleansed, astringent solutions, such as alum or sulphate of zinc, should be used in a similar manner, so as to impress the cleansed mucous membrane; and strongly impregnated with detergents, permanganate of potassa, carbolic acid, chlorinated soda, etc., if there is any offensive odor about the parts. The protrusions of mucous membrane should be cauterized or torn off, and dead bone be removed by surgical operation. Scrofulous patients should be placed upon the use of cod-liver oil and the phosphates, and syphilitic subjects upon iodide of potassium; and tonics and stimulants should be given where the general system is depressed. Protracted and persistent treatment of this kind is requisite for success.

EPISTAXIS.

Bleeding from the nose may be traumatic or idiopathic, or may depend upon disease. It is restrained by the local application of cold and astringents, by compressing the nostrils, by arresting bleeding, in extreme cases, by ligature; in short, by all the methods employed for restraining hemorrhage elsewhere. Where ordinary means do not suffice, a tampon is introduced into the posterior nares from the mouth, by means of Bellocq's canula, or some substitute for it, and secured by threads to a plug in the nostril. These tampons should not be retained in position more than forty-eight hours at a time, and if the epistaxis recurs in the removal, fresh ones should be applied.

The patient should be kept at rest, and all movements which favor the continuance or reproduction of hemorrhage are to be interdicted. At the same time systemic remedies are to be administered to favor the contraction of the arterioles; such, for example, as ergot, iron, turpentine, etc.

OCCLUSION OF THE NOSTRILS.

The nostrils may be occluded congenitally, or may become so as the result of accident or disease. The occlusion may consist simply in adhesion of the integument, or in the presence of an intervening membrane of cutaneous and mucous tissue, or even of fibroid tissue. Fracture of the nasal bones may be productive of occlusion.

In the treatment of this condition the offending tissues should be divided or removed, and the passages thus made kept pervious by the insertion of tubes or tampons until healing has been completed; any subsequent contraction being overcome by systematic dilatation.

OCCLUSION OF THE POSTERIOR NARES.

This is usually congenital. The obstruction may consist of fibrous tissue merely, or of bone also. The use of the probe will establish the diagnosis.

A passage through the parts is made by boring through them with a sharp steel instrument, or by the galvanic cautery, and is then maintained patulous by the frequent introduction and occasional retention of metallic dilators.

INFILTRATION OF THE SIDES OF THE VOMER.

The mucous membrane of the vomer is apt to become infiltrated, or pushed off by a sub-mucous infiltration, in inflammatory affections of the nasal passages. The lecturer was the first to draw attention to this condition, which is recognized upon rhinoscopic examination by the appearance of whitish and puffy tumors, more or less symmetrical, on either side of the vomer. The symptoms of the affection are those of obstruction to nasal respiration, and an uncomfortable sensation in the parts.

The treatment consists in destroying them by caustic applications or pulling them away by means of suitably curved forceps.

DEVIATION OF THE SEPTUM.

These are sometimes congenital, sometimes produced by disease, or the presence of tumors. In some instances it becomes advisable to attempt the restoration to the middle line. This is accomplished by the insertion of metallic tubes, compressed sponge, or laminaria tents, which are kept in daily for several hours at a time.

A so-called periosteal resection is sometimes performed for the relief of the deformity. A flap of mucous membrane is raised from the cartilage; the cartilage is thinned down until it can be pressed into the middle line; the flap is replaced, and the parts kept in position by sponges in the nostrils.

The unpleasant sensations of the patient are some-

times relieved by cutting out a piece of the septum, and thus establishing a passage for respiration on both sides.

Sometimes the cartilaginous septum is separated from the bone by subcutaneous division, after tamponing the nostrils, and the whole nose pulled over to the opposite side and retained by adhesive strips. Sometimes the nose is divided in the middle line, and the cartilage resected.

FOREIGN BODIES IN THE NASAL PASSAGES.

Foreign bodies are frequently inserted into the nasal fossæ by children; and if they are discovered early, they are very readily removed. But they may become impacted, and in time give rise to an irritating and offensive discharge. If the foreign body be of a comparatively large size, or be of such a character as to become swollen at the point of impaction, the nose will be distended out of its normal shape, and there will be increased severity of the pain and other local symptoms.

The presence of a foreign body in the nostrils usually produces inflammatory reaction, which is very apt to take on the appearances of a chronic coryza, with copious secretion of pus; terminating in ulceration, if not actual necrosis, of the parts against which the foreign body lodges.

When foreign bodies are retained for a long time within the nasal cavities, they are apt to become incrusted with the saline portions of the altered secretions to which these irritants give rise, and thus are formed the rhinoliths or nasal calculi sometimes met with in this region.

Sometimes the foreign body finds its way into the frontal sinus, especially when it is an insect or ascaris, producing intense frontal pain, headache, and even delirium, which may terminate fatally.

The earliest possible removal of the foreign body from the nostrils is the treatment that should be adopted in every case. Sometimes it can be dislodged by exciting the act of sneezing by the use of sternutatories. The injection of a strong stream of water through the nostril from behind forwards by means of the posterior nasal syringe, or by Thudichum's douche passed from the opposite nostril, will often suffice to expel the foreign body; and these simple and harmless measures should be tried in every case before resorting to more violent extractive efforts with the forceps and other instruments. Curved bougies and catheters are frequently serviceable, when passed forwards from the pharynx, in pushing the obstacle towards the exterior. External incisions, and even division of the nose, may become necessary for the removal of an impacted foreign body, when the usual means of extraction have proved unsuccessful.

Tumors, or foreign bodies, or parasites, in the frontal sinuses may require trepanning of the frontal bone; or access may be gained to these cavities by division of the nose at its root, and turning it over upon the face.

RHINOLITHS.

Calculi are occasionally met with in the nasal fossæ; their origin being generally due to the retention of some small foreign body which serves as a nucleus for the deposit of calcareous matter in successive layers. These rhinoliths are generally movable, varying in size from that of a pea to that of a hazel-nut, and in some instances completely obstructing the nostril. They are attended with the ordinary symptoms of obstruction, irritation, nasal and frontal pain, and a muco-purulent discharge.

The treatment consists in the removal of the concretions, an operation usually easily performed by the ordinary forceps. When the calculus is very large, crushing may have to be first performed.

ORIGINAL COMMUNICATIONS.

A NEW INSTRUMENT FOR TREATING DISEASES OF THE NECK AND CAVITY OF THE WOMB.

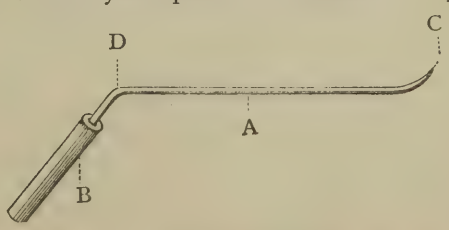
BY H. E. WOODBURY, M.D.,
Washington, D.C.

THE object of this paper is to introduce to the profession an instrument, simple in construction, and one that has proved valuable in my own practice. I desire that others may test it, believing that the physician as well as the patient will appreciate its value. It was designed and constructed to supply a desideratum in uterine therapeutics, patent to every physician who has encountered in practice those persistent and most troublesome diseases, endocervicitis and endometritis.

Having used the pencils of lunar caustic and of potash, as directed by our best authorities and practised by our most skilful physicians, I am free to confess that I was dissatisfied with the results of this mode of treatment, and felt that some means should be devised to promote a more rapid cure in such cases.

Weighing the matter well in my own mind, I concluded that the cause of the prolonged treatment under the old method was to be found in the fact that the medicinal agents employed were not brought thoroughly in contact with the diseased surfaces. In order to make the applications to the parts affected more thorough, I constructed the instrument I am about to describe, which I term the *Uterine Injector*. Whether by its use this end is accomplished I leave it for the profession to decide.

The instrument is simple, and easily made. Any physician can manufacture it for himself, as I have done for two years past. It consists of a piece



of glass tube (A), calibre of catheter No. 8 or 10, bent by heating in the flame of a spirit-lamp, as

shown in the diagram, drawn out to a point, and having a capillary opening (C) in the end. The edges of this opening are perfectly rounded by melting slightly in the flame. If too much heat be applied, the aperture will be closed. This tube is six or seven inches in length. Attached to the other end is a piece of rubber tubing (B), the extremity of which is closed so as to be air-tight. The curve near the point of the instrument should correspond to the curvature of the neck and cavity, and the angular bend at D is to prevent the hand from obstructing the view when the instrument is used.

By compressing the rubber (B) we exhaust the air in the tube,—on the principle of the syringe,—and, introducing the pointed end into a bottle of acid, iodine, or any other fluid, then releasing the rubber from pressure, we can take into the tube whatever quantity of the liquid we desire to use. The instrument is introduced into the neck or cavity of the womb, through the speculum, and its contents discharged slowly by compressing the rubber tube (B).

I believe that this simple contrivance will commend itself to the profession from the following considerations:

1. Its adaptation to the purposes for which it is designed.

2. The thorough manner in which, by its aid, applications may be made to all parts of the neck and cavity of the organ.

3. The convenience of the instrument, which prevents the hand of the operator from coming in contact with the acids or fluids used.

4. The precision with which the amount of fluid to be used can be regulated,—in the majority of cases only a few drops being required.

5. From the nature of the materials used in its construction, it is not likely to be acted upon by the strong acids, nor will it easily get out of repair.

I have been using the uterine injector in my practice for more than two years, and during that period have succeeded in curing my cases in less than one-half the time required by the old nitrate of silver treatment,—a method I had fully tested previous to the construction of my instrument.

The following are the remedies upon which I most rely: nitric acid; carbolic acid; tincture of iodine; extract of hemlock; tannic acid and glycerine.

Modus operandi.—Introducing the speculum,—I prefer Stover's, for I can use it as a retractor if the vaginal walls be lax,—I first explore the neck and cavity with the uterine sound, to satisfy myself as to the extent of the ulceration. After this I thoroughly remove the secretions from the parts. I then pass the injector—charged with a few drops of the fluid I desire to use—into the neck or cavity of the organ, as the case may require, and *very slowly* inject the fluid, *gradually removing the instrument during the act,* in order to make the application cover all of the affected surface. Finally I pass through the speculum a plug of cotton,—the size of which varies according to the laxity of the vaginal walls,—to which a fine strong cord is attached. This plug is saturated with carbolic acid and olive oil or glycerine,—one part of the former to five or six of the latter,—and is left in contact with the os uteri for from twelve to twenty hours, when the patient by means of the cord removes it herself, and injects a weak solution of sulphate of zinc, or Castile soap and water.

During the first fortnight of treatment I make an application every other day,—afterwards at longer intervals, as the necessities of the case may require. I always order uterine and general tonics in these cases, and I am convinced that they generally prove valuable auxiliaries to the local treatment advocated in this paper, and fortify the system against subsequent attacks of these annoying and debilitating diseases.

I know that there is a great diversity of opinion in the profession as to the expediency of intra-uterine injections, and feel constrained to refer to the views, relative to this subject, of one to whom we are under many obligations for valuable contributions to our science in the past.

Dr. Gaillard Thomas, in the *New York Medical Journal,* August, 1870, says of them, "They have done, and are going to do, a great deal of harm." What evidence does he adduce in proof of this? He states that he injected five drops into the uterine cavity, and it caused a tedious peritonitis, the patient barely escaping with her life.

He adds, "But it will be said the cervix was not dilated in this case," and goes on to state that dilatation is itself attended with danger, citing a case in which he practised it, using Peaslee's dilators, and his patient died of peritonitis in one week. "I think," he says, "the mischief was done by the dilatation of the neck of the uterus. Yet I am very sure that the dilators were passed with requisite skill, for I spend much of my time in this practice, and this operation is one to which I have constant resort."

Now, what does this all prove? Simply that the doctor had an unfortunate case,—a case in which he believed that dilatation of the cervix lighted up a peritoneal inflammation, without any injection whatever; and yet he says that he constantly resorts to this operation, attended with danger as he knows it to be; while he "will not use intra-uterine injections, even for the hemorrhage of abortion."

Again, in the case where his patient barely escaped with her life, there was, without doubt, a diseased condition of the Fallopian tubes,—dilatation, perhaps, which might have given rise to the untoward results of the operation. We have read or heard of a case in which a uterine sound passed into and through an unimpregnated uterus to a distance of four or five inches. The instrument was repeatedly passed, in the presence of several reliable physicians. Where did it go? Where could it go, but into a dilated Fallopian tube? Such cases, of course, are exceptional, and to our mind they offer no argument against intra-uterine injections.

A man died from erysipelas, developed by vaccination, a few years ago, in my own neighborhood. Is this an argument against vaccination? A woman dies in confinement when the forceps have been used to complete the delivery. Should we therefore dispense with this valuable obstetrical instru-

ment? Tracheotomy, lithotomy, and many other operations are sometimes followed by death. Are we therefore to fold our hands and refuse to use the knife? If so, there will be an end to all progress in the healing art; and the noblest of the professions will verily become a by-word and a reproach among men.

If the use of such an instrument be objected to on the ground that danger attends the injection of the cavity of the womb, I think such an objection may be set aside by the recorded experience of such men as Dr. Barnes of London, the late Dr. Simpson of Edinburgh, and Dr. Peaslee of New York.

At a meeting of the Medical Society of the County of New York, a few years since, the latter gentleman, referring to the injection of a solution of persulphate of iron in metrorrhagia, said, "Having employed the agent in perhaps one hundred cases, I have never seen any harm result, except that in one case it gave great pain." Dr. P.'s experience fully confirms the statements of Drs. Barnes and Simpson as to the safety of the operation, even where a comparatively large quantity of fluid is injected. The instrument I use will contain but from fifteen to twenty minims; I inject from three to ten drops.

After the manner indicated in this paper, I have treated every case of endo-cervicitis or ulceration that has occurred in my practice for more than two years, and in no single case have any unpleasant results followed. I believe that when the acid or iodine is injected in a small quantity *and slowly* it is speedily and entirely taken up by the diseased tissues with which it comes in contact, and acts far more efficiently and rapidly than the pencil of caustic, which by coagulating the albuminous compounds on the surface forms a sort of white film, beneath which its effect is not apt to extend. A remark that is true in regard to many other instruments, now properly appreciated by the profession, applies with equal force to this: judgment and discretion should be exercised in using it. In reckless or inexperienced hands, no instrument is more dangerous than the lancet, the scalpel, or the catheter; and yet what intelligent physician would therefore ignore their use?

Trusting that by this contribution to uterine therapeutics I may in some degree be instrumental in advancing uterine surgery and in relieving thereby the ills of the weaker sex, I present my uterine injector to the profession, with the hope that in their hands it may prove as valuable an aid as it has so far proved in my own.

WASHINGTON, D.C., Jan. 1, 1873.

NOTE.—Without taking the trouble to go over my note-book, I have written down from memory more than twenty names of patients treated by me after the method set forth in this paper, in all of which the treatment proved safe and successful.

NOTHING is so successful as success. If a physician is supposed to have a large practice, everybody will contribute to make it larger; just as a man who is reputed rich can always borrow.

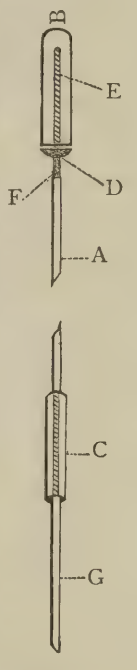
MEERSCHAUM PROBE.

BY H. CULBERTSON,

Late Assistant-Surgeon, U. S. Army.

IN 1864 I invented this probe, and lately have made an addition to it for the detection of clothing in wounds. The following is the description:

The shaft A is in length from D to C 4½ inches, and in diameter that of a medium-sized probe. At D is a shoulder ⅛ inch in diameter, which is securely attached to the shaft. E is the continuation of the shaft A, is ⅜ inch in length, $\frac{1}{16}$ inch in diameter, and a thread is cut on its surface the entire length. B is a round tip of meerschaum, 3 lines in diameter and 6 lines in length, which is saturated with a cold solution of the ferridcyanide of potassium,—red prussiate of potassa,—and which is drilled out in its centre longitudinally ⅜ of an inch, the opening being $\frac{1}{16}$ of an inch, strong, in diameter.



The surface of the shaft from F to D, as well as the exposed surface of the shoulder D, is roughened on the shaft longitudinally for the length of ¼ inch and on the curved surface of the shoulder D. At C is represented a cylinder, in which is cut a thread, and which receives the ends of the shafts A G. The shaft G is 4½ inches in length. The entire probe (except the tip) is made of silver, and is about 9½ inches in length.

The tip is attached to the shaft E thus. Wrap it with paper, over this bind it firmly with thread, fill its cavity with finely-pulverized gum shellac, packing this with a pin; heat the shaft to a dull red, and immediately insert it into the cavity (filled with the gum) of the tip, push it quickly down, and hold it firmly against the shoulder D until the gum has cooled. The tip can then be dressed down, round and smooth, with fine sand-paper.

The meerschaum can be procured from a large-sized cigar-holder. One of the best tests of the purity of the article is its floating on water for a time, while plaster of Paris will immediately sink.

Lead leaves the usual lead-mark on the tip, as well as a slight indentation beneath the mark.

Iron, in either a recent or an old wound, leaves on the tip a blue trace; but, if the fragment of this metal is covered with an albuminous coating, no coloration will be shown.

Denuded bone, or any hard foreign body in the wound, when the tip is made to impinge against it, will leave a *scratch*. This quality is also useful in the examination of diseased joints where cartilages are ulcerated and bone exposed in the cavity of the joint.

If clothing be in the wound, and the heel of the tip (at F) be revolved against it, fibres of the material may be retained at this rough part of the

probe, and a strong glass or the microscope will complete the diagnosis.

In a case treated in 1865, after passing this probe beneath the scapula, it came out colored a deep black. On removing a Minié ball from beneath that bone, it was found invested with a portion of soldier's blue cloth.

Late in 1864 an officer informed me that by the aid of this probe, after the failure of other means of diagnosis, a fragment of shell was detected near his elbow, and was removed by a Dr. Smith, of the United States army.

A solution of the red prussiate of potassa, 20 grs. to the ounce, will sufficiently saturate the tip by leaving the latter in the fluid three days.

Before inserting the tip in a wound, wipe off the brown coating on its surface. In using the probe, revolve the tip on its axis, or move it to and fro upon its side, or laterally upon the end, against the foreign body. On withdrawing it from the wound, do not wash the tip until it has been carefully inspected with the aid of a glass. Finally, wash it in clear water, and, when dry, rub out the traces with fine sand-paper and polish with unglazed paper. Before using, however, the probe should be inspected with a glass, to be sure that there are no fibres of clothing or traces upon it.

With careful usage, one of these tips will last several years, and any one can affix another when necessary.

One end of the probe is made in the usual form.

Though using this probe often since 1864, I have seen no ill results following its employment.

ZANESVILLE, OHIO, December 16, 1872.

NOTES OF HOSPITAL PRACTICE.

EPISCOPAL HOSPITAL.

SERVICE OF SAMUEL ASHHURST, M.D.

A CASE OF NECROSIS OF THE CRANIAL BONES IN CONNECTION WITH DISEASE OF THE MASTOID CELLS.

IN the year 1868, George Clark, aged 12, became deaf, and in 1870 a discharge was established from both ears, from which time the hearing was very generally improved by the operation of syringing the meatus. About the middle of June, 1872, after a voyage from Boston to Truro, N.S., and return, he was sick for a week with "diarrhœa, sick stomach, and pain in the bones." He was quite well during the rest of the summer, spending part of it in a cork-factory in Boston, and towards its close working in a saw-mill at Bath, Maine. On September 27, 1872, he left Bath as a seaman, and upon his arrival at Philadelphia, September 30, was taken sick with diarrhœa and vomiting, and for the first time a swelling was noticed at the back of the right ear.

On October 5, 1872, he was admitted into the Episcopal Hospital, Philadelphia. A water-dressing was applied, and he was ordered fifteen drops of the tincture of the chloride of iron three times a day.

October 6.—There is a discharge from the right ear, which appears to come from the side rather than from the bottom of the meatus.

October 7.—The patient is confined to bed, and presents the following symptoms. He is almost entirely deaf. There is much puffiness of the eyelids and face on the right side, and the upper lip is swelled. The posterior portion of the scalp on the right side is elevated, and there is deep fluctuation present; the discharge from the ear has stopped.

October 9.—Discharge from the ear is re-established; there is less œdema of the face; his general condition is good. An opening was made through the scalp, and a considerable amount of sanious pus evacuated.

October 10.—There is continued discharge from the incision, and from both ears.

October 12.—Upon introducing a probe into the opening made a few days since, the skull is found to be denuded of periosteum for a space three inches in diameter. The discharge continues; pulse 120; skin hot; tongue moderately furred; there are no cerebral symptoms. A grave prognosis was made. He was ordered one pint of milk punch through the day, good diet, and beef-tea without stint. Pulse 120. Temperature in axilla 104°.

October 13, 10 A.M.—Pulse 140; temperature 104°. He was ordered six grains of sulphate of quinia, and twenty-four ounces of punch in the twenty-four hours. P.M. pulse 120; temperature 95°. (This was taken by a reliable nurse.)

October 14, 8 A.M.—Pulse 128; temperature 98°. One P.M., pulse 76; temperature 96.4°. Six P.M., pulse 136; temperature 104°. The pulse is of good volume, but much increased in frequency upon slight exertion. Here and there are dusky congested spots in the skin, and there are sudamina scattered over the surface of the abdomen. The *tâche cérébrale* is readily produced, but there is no other symptom pointing directly to the brain, his intellect being clear. His bowels are regular; the spleen is somewhat enlarged. The condition of the scalp is not materially changed.

October 15, A.M.—Pulse 148; temperature 98°. P.M., pulse 120; temperature 99.5°.

October 16, A.M.—General condition seems somewhat better. The congested appearance of the skin before referred to is now noticed to be confined to the left half of the body and the right leg. Owing to his deafness, it is not easy to examine the state of his intelligence, but it seems clear, and there are no cerebral symptoms. Pulse 84; temperature 100.5°.

October 18.—General condition improved; discharge small in amount; appetite good; appears to be doing well. (The temperature was not taken, owing to breakage of the thermometer.)

October 20.—Complains of chilliness. The congested appearance of the skin is again evident, and is confined, as before, to the left half of the body and the right leg. Has vomited once this morning.

October 21.—Congestion of skin continues; vomited again after breakfast. Pulse 120; temperature 104.5°.

October 22.—Limited congestions remain. A.M., pulse 120; temperature 104.5°. P.M., pulse 136; temperature 104°.

October 23.—Pulse 140; temperature 104°.

October 24.—The discharge from the incision has gradually increased since the 18th instant, and is now copious. There is considerable bagging of the scalp, for which a compress was applied. Complains of pain down the neck and in the upper part of the back: there is marked tenderness upon pressure over these regions. Sleeps naturally at times during the day; morphia is given at night.

October 25.—To-day there is evident pain in the neck upon rotation of the head. The local congestions continue; there are no new head symptoms, if indeed those already referred to are such. A counter-opening was made in the most dependent portion of the abscess, through which a free discharge of pus took place.

October 27, A.M.—Pulse 136; temperature 102°. P.M., pulse 120; temperature 98°.

October 28.—There is a free discharge from the lower opening in the scalp, and movement of the head causes less pain. A.M., pulse 140; temperature 102°. P.M., pulse 128; temperature 100°.

October 29.—Profuse discharge from the counter-opening. Pulse 120; temperature 105°.

October 31.—Has had a chill this morning. The peculiar congestion so often referred to is especially well marked. Discharge very abundant. Pulse 156; temperature 106°. Quinine increased to fifteen grains daily.

November 2.—Has had several convulsions, and at the time of my morning visit he lay moaning, in an unconscious condition. The right pupil was widely dilated, but the left was normal in size; both were insensitive. He has occasionally slight convulsions. It was decided to trephine with a small crown through the necrosed bone, in the hope of allowing the escape of any confined pus. The operation was followed by a cessation of convulsions, and normal contraction of the dilated pupil, although the escape of pus from beneath the bone was not very evident, as the parts were already so thoroughly bathed in the discharges. He gradually sank, and died quietly on the evening of November 3.

The post-mortem examination was made the next day. The membranes of the brain were very moderately injected on their posterior half. The occipital, temporal, and parietal bones were found to be extensively necrosed. The disease was limited externally to the inferior angle of the right parietal bone, and to the temporal bone. Internally it had invaded the occipital bone in the region of the right lateral sinus, considerable erosion and excavation having taken place there, which extended forward to the under surface of the petrous portion of the temporal bone, and in this locality two perforations, about one-fourth of an inch in diameter, had penetrated to the exterior of the skull; patches of superficial erosion were noticed upon the parietal and temporal bones, stained and slightly roughened. Externally the inferior angle of the parietal bone had undergone exfoliation, as was also the case with the squamous portion of the temporal. The mastoid process was extensively eroded, especially at its upper part, where the perforations from within were situated.

The case presents some points of interest, among which may be instanced the great variations in the temperature, and the occurrence of well-marked and persistent circumscribed congestion of the skin of the left trunk and right lower limb. I am able to furnish no satisfactory explanation for either of these phenomena, but think it well to place them upon record as clinical facts which may prove of value on comparison with other cases.

The question of interference by operation was anxiously debated, but it was thought best to await the efforts of nature so long as no distinct symptoms of compression appeared. The operation was undertaken without any defined hope of a successful result. It was, however, followed by partial amelioration of the symptoms. The trephine was applied nearly over the lateral sinus, in the expectation that the dead bone would be found separated from the sinus by lymph, and the latter so plugged with coagula as to avert all danger of hemorrhage.

The specimen affords a good illustration of how easily a trephine may be applied to a diseased external table and yet miss an internal abscess. Had I known of the existence of the large perforations revealed in the specimen, no operation would have been undertaken, as mechanical compression could hardly have existed. It is certainly remarkable that with such extensive disease of the bones there should have been so little meningitis.

THE INNERVATION OF THE LACHRYMAL GLANDS (*Lancet*, April 5).—In his experiments on this subject, Dr. Demtschenko (*Pflüger's Archiv*, Sept. 1872) has operated on animals narcotized by means of morphia. The subjects were dogs, cats, and rabbits. The electric stimulus was applied by means of Dubois-Reymond's apparatus. The quantity of fluid discharged by the lachrymal glands was estimated by the number of square centimetres of blotting-paper that were moistened. In the dog and cat the lachrymal nerve could be reached from the orbit; but in the rabbit the skull had to be opened. The chief results obtained by Demtschenko were that the temporo-malar nerve exercises no influence on the lachrymal gland. Excitation of the great sympathetic augments the secretion; it augments also the quantity of fluid secreted by the conjunctiva, even when the nerve is irritated after ablation of the gland. The augmented flow of tears which follows irritation of a large number of cranial nerves (as the frontal, infra-orbital, nasal, lingual, glosso-pharyngeal, and pneumogastric) is not interfered with by section of the sympathetic, but is stopped directly by section of the lachrymal. This reflex action is not wholly abolished during the sleep induced by chloroform. The author proceeds to compare the results of irritation of the sympathetic and of the fifth on the quantity and quality of the tears. The great violence requisite to expose the fifth throws a doubt upon the value of these experiments. The tears, however, were clear and limpid when the fifth was irritated, but cloudy when the sympathetic was excited. On the whole, he thinks he may conclude from these and other experiments that the great sympathetic presides over the normal humectation of the globe of the eye; and this is supported by pathological facts, since the eyes of patients suffering from paralysis of the fifth retain their proper moisture, though the power of shedding tears is abolished. Disturbances of the circulation caused variations in the lachrymal secretion. After ligation of the carotid artery, irritation of the lachrymal nerve caused a less abundant flow of tears than on the sound side. Ligation of the veins increased the flow of tears. All troubles of the respiration caused increased flow.

A RAILWAY CASE (*Lancet*, April 5).—A difficult railway case, developing a difference of opinion among medical men, was tried at the Carnarvon Assizes. On the one side, it was alleged that the plaintiff, a widow with five children, making 30*s*. a week or more before the accident, was paralyzed on the right side, and would never recover from it; on the part of the company, "equally eminent men" maintained that the paralysis was hysterical, and would disappear as soon as the anxiety connected with the trial was over. There had been no hysteria previous to the accident. The jury was puzzled by the discrepancy of medical opinion. After two attempts to agree, the parties concerned agreed to a verdict for the plaintiff for £600. The public may easily overrate the unreasonableness of a difference of opinion in such cases. Strictly speaking, no absolute opinion of the permanence of such injuries can be arrived at. It follows that one side takes the extremely favorable view, and the other the extremely unfavorable. The difficulty is in the nature of the facts and in the essential obscurity of nervous states.

CURE OF NÆVI BY MONSEL'S SOLUTION APPLIED EXTERNALLY.—Dr. Jacob Geiger, of St. Joseph, Mo., records (in *The American Practitioner* for April) a case in which two nævi, one occupying the perineum and part of the scrotum, and the other seated on the abdomen, of a child six months old, were completely removed, in less than one month, by painting twice a day with a mixture of equal parts of glycerine and a strong solution of persulphate of iron.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 26, 1873.

EDITORIAL.

MISTAKEN LIBERALITY.

IT is stated in the daily papers that "two of the Departments" of the Michigan University, at Ann Arbor, have been placed under the control of homœopathists. Exactly what this means we do not know, although well aware that for many years the adherents of homœopathy have been working hard to get a footing in that school, which is, we believe, the only State institution of the kind in the country. But we presume that chairs for the teaching of Hahnemann's doctrines have been established, the professors holding equal rank with members of the previously existing Faculty.

Now, it would seem at first sight a most just and reasonable thing that every faith should have a hearing, and that each student should be allowed to choose that mode of practice which most commended itself to his judgment. And yet, were this plan followed up, Thompsonianism, eclecticism, hydropathy, and every other *ism* and *pathy*, might demand a chance to present its claims. In thirty years homœopathy has failed to impress itself in any degree upon medical opinions or practice; in the world of science it and its adherents are alike unknown. The dogma upon which it is based is avowedly untenable in emergencies. Hence it is idle to claim for it a place as a "department" of medicine.

We trust that the regular Faculty of the Michigan University will have the spirit to refuse utterly this unequal yoking, and to resign in a body if the attempt is made to force it upon them. They would have the moral support of the entire profession in so doing, and, even if the school should be left in the hands of homœopathists, the evil would be far less than that of a seeming fraternization with quackery.

THE REMOVAL OF THE ALMSHOUSE.

AMONG other public changes, some of which are for the better and some for the worse, it is proposed to abandon the present site of the Almshouse, building another in some less central position. Upon what pretext so needless and so very expensive a job is urged on the authorities, we do not know. The "palace for paupers," as Miss Martineau called it, has cost very large sums of money, both for its original construction and for repairs and improvements. It is large enough to afford shelter to a great many able-bodied men and women who ought to be made to earn their living. It is not in the way of projected streets or other public benefits which are at the present time imperatively needed. The ground it occupies has not yet so risen in value that the mere sale of it would pay the cost of the new structure.

We cannot help feeling a strong suspicion that the whole affair has arisen, not out of any public want, but out of private greed. A plan like this seemed to some contractor to afford the best available opportunity for a fresh grab at the city's purse, and he set things in train to get it on foot and the controlling strings in his hands. We believe that for the present the scheme is in abeyance, but we do not think that it has been so completely "squelched" as it deserves to be. Many things cry aloud for betterment before this matter need be thought of.

A VERY UNDESIRABLE REPEAL.

A BILL now before the Governor of this State will, if it becomes a law, affect very injuriously the sanitary interests of the growing portions of Philadelphia. It is, in brief, to repeal part of an act passed in 1855, which forbade the erection of any new house or building on any street, court, or alley of less than twenty feet in width, unless such house were set back so as to increase the width of the street, court, or alley to at least twenty feet.

Another portion of the same act of 1855 provided that no new street should be laid out with a width of less than twenty-five feet, and that every new dwelling should have an open space at least

twelve feet square either in the rear or at the side of it.

To the medical profession, who know too well the evils attendant upon the crowding together of the dwellings of the poor, the benefit of such legal enactments, properly carried out, must be patent; and it is difficult to see on what grounds the abrogation of laws so manifestly wholesome could be proposed. We most earnestly hope that the Governor will withhold his sanction from a measure which, for the pecuniary interest of a few, would sacrifice the health of many.

LEADING ARTICLES.

WHO ARE EXPERTS?

AMONG the topics that, at different times, have engaged the attention both of jurists and physicians, there is probably none of more importance, and none that has occasioned greater difficulty in trials, than the subject of *expert evidence*. In both civil and criminal cases, where the gravest interests are at issue, the final result frequently depends most materially upon the character of the expert testimony. It becomes, then, a question of the utmost consequence to understand the proper meaning of this term, and what is its significance when applied to evidence given in a court of justice.

The term "expert witness" literally signifies a *skilled* witness—one who has an accurate knowledge of the matter under consideration. Such witnesses are "chosen on account of their special knowledge or skill in particular matters, to testify, or make a report embodying their opinions" (Elwell). The "expert" witness does not testify to *facts*, like the ordinary witness; but he gives his *opinion* based upon facts that have been testified to by others. It is his special function to carefully weigh all these facts, to sit in calm judgment upon them, and to deduce conclusions from them, which he delivers to the court and jury as his *opinions*.

If he is an honest man, and delivers his opinions according to his oath "to declare the whole truth," he need not be afraid of the danger of committing a mistake in delivering his testimony, for he is simply *giving his opinion*, and he cannot be mistaken *as to that*, however he might be mistaken as to supposed facts. We presume that there can be nothing within the sphere of human intelligence more certain than the individual *opinion* which a man forms (supposing he forms one at all) after a careful consideration of a catenation of facts. Observe, we do not say that this opinion is necessarily or absolutely correct in the abstract,—that is not the question; we merely affirm that he cannot be mistaken as to the fact of its being his opinion; and *that* is all he swears to. As to its *correctness*, the jury must decide.

No doubt, many conscientious men fall into error just on this very point, and they are reluctant to testify as to matters of opinion, under the mistaken idea that they might commit a fatal blunder in a capital case, and perhaps, through their "opinion," be the unhappy means of sending a fellow-being to the gallows. Unquestionably, the position of the expert witness on such a solemn occasion is a most trying and responsible one. Keenly alive to the dreadful issue that may be hanging on his evidence, he must nevertheless deliver his opinions with all truthfulness. In the language of Dr. Percival, "he should use his best endeavors that his mind be clear and collected, unawed by fear, and uninfluenced by favor or enmity."

For the *consequences* of his opinions, he should however understand that he is in no wise responsible. He dare not suppress aught of what he conscientiously believes to be *the truth*, no matter what may be the result to the accused.

How unspeakably important, then, it is that the individual who assumes the functions of the "expert" witness in a criminal trial, should so clearly understand the matter on which he is to testify, and be so familiar with its every detail, as to preclude all possibility of error on his part! Yet it is notorious that nearly every criminal trial in our country is hampered, if not disgraced, by what has been sneeringly called by the newspapers the "war of the experts." The public have come to look upon it as a matter of course that the professional "experts" summoned for the different sides shall necessarily wage a fierce and bitter warfare against each other; and, regarding all the so-called experts as being on a precise equality, they allow the testimony of the one to neutralize that of the other; and they are consequently inclined to reject the whole as entirely superfluous, if not positively worthless,—a result which we feel assured is not unfrequently reached by the jury as well as the public—to the great and manifest disparagement of justice.

Let us, by way of illustration, suppose the case to be one of poisoning—real or alleged. Now, in order to substantiate the charge of poison, it is not enough that the symptoms should have resembled those of the alleged poison, since all authorities agree that there are no symptoms exclusively characteristic of any poison (for, if so, there would be

no occasion to make a chemical analysis); neither is it sufficient that the post-mortem lesions should resemble those attributed to the alleged poison, since it is notorious that these lesions are exactly simulated by disease. A third factor—the chemical analysis—must enter into the consideration. If all these three factors harmonize (supposing the chemical examination to have been properly made), we think that the proof of poisoning may be considered as established. But we by no means wish to be understood as maintaining that this proof can never be made out without the chemical evidence. On the contrary, there are cases where, for various reasons, this last means of proof is impossible, but where the whole circumstances of the case—medical and moral—point so unequivocally to poison as to leave no reasonable doubt as to its administration. These, however, are exceptional cases, and they demand the most searching investigation before arriving at a final decision.

Again, we may suppose another case—a non-fatal one,—where no chemical analysis has been made of any of the suspected food or drink, nor of any of the excreta of the body. For some reason, however, a suspicion has been excited against the accused party. Circumstances, not yet explained, have combined to give a coloring to the suspicion, and an arrest and a trial follow. Now, it is well known that the most innocent persons may, through a combination of circumstances, be thrown into the position of, apparently, the most positive guilt. It is this fact that constitutes the danger of a too exclusive reliance upon mere circumstantial evidence. In the above case, suppose that the "expert" witnesses for the prosecution do not fully answer to the standard which we have adopted and explained in the opening of this article; they are, to be sure, highly respectable physicians—it may be, men of large experience as general practitioners, but confessedly they are not "toxicologists,"—they have not made the subject of *poisons* in all their relations a *special* study; and shall they, simply because they are called "doctors," presume to thrust themselves into the witness-box, and swear away the life or liberty of a fellow-being exclusively on what *they* take to be the infallible "symptoms" of the alleged poison, when the highest toxicological authorities declare to us that there are no such symptoms? Or should the witness happen to be a *chemical* "expert," if he content himself with a partial, unexhaustive examination of some collateral material alleged to be connected with the accused party, and if he proceed to draw positive conclusions as to the discovery of some poison, from such imperfect data, can we safely admit his testimony as strictly coming up to the proper standard of "expert" evidence?

Let us test this question by reference to a civil case: suppose it relates to the strength and resistance of steam-boilers, connected with an action for damages in a case of boiler-exposion, we would hardly look to an ordinary blacksmith—no matter how skilful a mechanic he might be, or how well acquainted with the general properties of iron—as the fittest person to enlighten the court and jury upon the questions at issue; we should rather select our "expert" from among practical boiler-makers, or practical engineers. In like manner, if the question pertains to the strength of building-materials, in a case of alleged want of skill in the construction of some large public edifice, which had given way and occasioned the loss of human life, we should be far more likely to appeal to the skilful architect or the practical builder, for an "expert" opinion, than to a common carpenter or bricklayer, although the latter may be well acquainted with the ordinary properties of wood, brick, and stone. On what higher ground, then, we ask, should the mere general practitioner of medicine presume to offer himself as an "expert" in poison cases, and to contradict the testimony of those who may have devoted a life-long labor and research to this very study? A striking illustration in point is afforded in the case of the illustrious John Hunter, who, in the year 1781, was called upon as an expert to testify in the celebrated case of Sir Theodosius Boughton, who was poisoned with laurel-water by his brother-in-law, Donellan. Mr. Hunter was called for the defence, but his ignorance on the general subject of poisons caused him completely to break down on the cross-examination, leading to a mortifying failure on his part, and rather strengthening the case for the prosecution.

If only the same failure that happened to Hunter could be made to attend the presumptuous attempts of all pseudo-experts, it would be a happy circumstance for the cause of justice and humanity; but, unfortunately, this is not the case. Under our present faulty jurisprudence which permits any "doctor" to assume the character and functions of the expert, it constantly happens that a conflict of testimony occurs between the so-called skilled witnesses of the opposite sides, not because a difference of professional opinion is usually likely to exist between *genuine* experts, but because witnesses of unequal capacity and of unequal knowledge are opposed to one another,—the true against the false, the real against the counterfeit. But all this time the ignorant public and the no less ignorant jury

are made to believe that "one expert is just as good as another,"—as we happen to know a certain learned judge said in his charge to the jury,—although the one may be simply a village doctor, or perchance a city practitioner, but both equally unskilled in the mysteries of toxicology, whilst the other may be a Christison, an Orfila, a Taylor, or a Tardieu! Alas, for any hope of a righteous verdict from such a befogged jury! And alas, with such doctrine taught from high places, for the hope of making the public appreciate the true merits of the case!

This subject assumes a far more serious and important aspect when we add to what has just been said, the not uncommon fact that the pseudo-expert for the prosecution may possibly be prejudiced against the accused party, or against his counsel; or, it may be, he is hostile to the experts for the opposite side. Such a feeling, whether consciously or not, must of necessity warp and bias his judgment, and produce a distorted view of the facts of the case. This will undoubtedly lead him to give his "expert" opinion *against* the accused; and this ill-founded *opinion* will, in its turn, exert its baleful influence over the court and jury.

Now, such a state of things is simply monstrous, and it is fraught with real danger to the community. No one knows when he or she may become the victim of some combination of circumstances that may, for a while at least, cast its blighting shadow over their path, aspersing their character, or even threatening them with death! Heaven help the unfortunate who may get entangled in such coils, and be exposed to a public trial against such fearful odds! What could he expect from a jury, instructed as above mentioned from the bench, and bewildered and deceived as to the relative value of the "expert" testimony, by a crafty and unscrupulous counsel?

Is there any remedy for this really dangerous condition of affairs? None that we can see, until some change takes place in our faulty jurisprudence in the manner of selecting "expert" witnesses. So long as the courts assume the ground that "one expert is as good as another," and at the same time refuse the real expert the privilege of sustaining his opinions by reference to standard authorities in his own department,—the only possible method that we know, by which he can fortify his positions before the jury, and exhibit to them the superiority of *his* expert opinions,—so long as this is the case, we must abandon all expectation of fairness in jury-trials, and submit to the detraction of the real experts by some vulgar and abusive counsel, who, himself fully conscious of the superiority and power of the genuine expert on the opposite side, will endeavor to break down the dreaded influence of his evidence before the jury, by a fierce and malignant personal attack upon his professional and private character.

Several plans have, at different times, been proposed for remedying this abuse. The only one that occurs to us (and this seems scarcely feasible under our present system of selecting the juries) is to try all such cases before *educated* juries, by which we mean men who have a clear comprehension of the scientific points at issue, and who are capable of appreciating the difference between the testimony of a real and of a pseudo-expert.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held March 26, 1873, at 8 o'clock P.M.,

Dr. H. H. SMITH called the attention of the members to the treatment of hydrocele as he had practised it with very satisfactory results for several years. After alluding to the repeated failures of the injection, seton, etc., as usually practised, and the apprehension felt by many surgeons of hemorrhage in "excision of the sac," Dr. Smith stated that he had obtained cures in from ten to fourteen days, the patients sitting up on the third or fourth day, and had had no trouble from hemorrhage, by operating as follows. Etherize the patient, make the scrotum tense, incise the skin, dartos, and connective tissue carefully for from two to five inches in the long diameter of the tumor, until the tunica vaginalis is fully exposed, the blood-vessels being outside of the sac, or in the scrotal tissues. Having freed the testicle nearly from the scrotum, puncture the hydrocele with the bistoury, empty the sac, and then trim off with the scissors the anterior half of the tunica vaginalis testis, introduce a mesh into the lower end of the wound, and close the rest of it with the interrupted metallic suture. The cure is prompt and certain.

Dr. W. L. KNIGHT said he could sustain Dr. Smith in the remarks which he had just made, as he had recently operated in a case for him. The patient sat up on the fourth day; he walked about out-of-doors in two weeks, and within four weeks was able to attend to his usual active out-door duties. The operation was accompanied with but little pain or annoyance.

Dr. J. M. BARTON had treated a number of cases in the clinic of Jefferson Medical College, in which the seton had been used, and the patients were generally discharged in as short a time as that mentioned by Dr. Smith. In one case in private practice the patient attended to his ordinary business on the fifth day, the seton having been retained for three days.

Dr. A. D. HALL referred to a case of asthenopia in the person of a strongly-built, muscular young man, a student of theology. His complaint was that he could not see the types of his text-books distinctly. Only by bringing the page extremely near the eye could he see at all, and then the effort to do so caused great pain in the eyes and brows, which continued for an hour after.

There was slight injection of the conjunctivæ, and on

the left temple was an ancient scar of Heurteloup's leech, which had been applied by a Baltimore oculist during a week's stay in his private institution. His vision was not tested at that time.

Examination by the ophthalmoscope showed no changes in the fundus oculi; but there were evidences of both astigmatism and hyperopia. At twenty feet he could only make out No. 200 of Green's letters. This is a letter $3\frac{7}{10}$ of an inch broad, by $3\frac{5}{10}$ inches high. These measurements give a better idea of the low visual acuity. Both eyes were alike. He saw horizontal lines better than vertical ones. The addition of a convex glass of fourteen inches' focus reversed this state of affairs,—vertical lines came out distinctly, while the horizontal ones became dim. (This was shown by drawings upon the blackboard, by which the presence and amount of astigmatism were got at rather more quickly than by the ordinary methods in use. It was also so simple that it did not deter those wishing to undertake its investigation by a formidable array of detail.)

He was now given a convex cylindrical glass of fourteen inches' focus, with its axis vertical, and his vision rose to $\frac{20}{30}$. But he exerted his accommodation very powerfully, and to eliminate this element of error atropine solution of full strength was instilled. It was then found that the vision rose to $\frac{20}{30}$ for both eyes, with a convex cylinder of nine inches' focus, axis as above. After the effect of the atropia had passed off, it was found that this glass was too strong for steady use, as the habit of powerful accommodation was too old and strong to be so rudely broken in upon. But with a convex cylindrical glass of twelve inches' focus, its axis vertical, his vision was $\frac{20}{30}$, and with these glasses he could read No. $1\frac{1}{2}$ of Snellen's test-types (a little larger than printers' "diamond") at eleven inches, and as near as five inches, thus making his vision almost normal for distance, and quite so for near work. That astigmatism is quite common, those who are on the lookout for it will certainly agree. In 1862 Professor Donders, of Utrecht, found it in one of every thirty eyes that he examined. Although he had not the material immediately at hand to verify the assertion, still he was inclined to think that the average has risen in the course of the thorough ventilation the subject has had in the last decade.

In the above case, without the recognition of the fact that the weakness and irritation of the eyes were merely symptoms of an effect resulting from the tension of the ciliary and internal recti muscles in their effort to compensate for the irregular refraction of the cornea, we might have gone on prescribing until the "crack of doom" for an affection which could be cured then and there by the proper adaptation of glasses.

As the subject of sympathetic ophthalmia was one which always presented interest, and too often a melancholy one to both surgeon and patient, he would mention such a case which lately engaged his attention. It was one in which there could not be said to be any real sympathetic inflammation of the sound or uninjured eye. The condition of the eye was rather that of slight irritation; and yet, in spite of enucleation at once, in anticipation of what might come rather than from actual fear of what was present, this prompt removal of a possible source of trouble utterly failed to arrest a violent destructive process in the other eye.

The patient was a fine, bright young fellow of seventeen, engaged in a planing-mill at Kaighn's Point, N. J. Two days before Dr. H. saw him, he was struck by a flying piece of wood, $13\frac{1}{4}$ inches long, $\frac{3}{4}$ inch wide, and $\frac{1}{8}$ inch thick. This produced a perforating wound $\frac{1}{4}$ of an inch in length at the middle of the inner border of the left cornea, about 2‴ back of the sclerotic junction. There was moderate injection of the bulb. The cornea was dulled by the presence of blood and opaque-lens substance as viewed by oblique illumination.

Removal of the (in his view) hopelessly injured globe as a precautionary measure was not consented to by the patient or his friends.

Twelve days after this the eye seemed to be free from any active inflammation. The blood which had obscured the view of the anterior chamber having been absorbed, there was seen to be a partial dialysis or tearing away of the iris (for its upper third) from the ciliary body. The lens was opaque, and its inner edge dislocated forward. A fortnight later he could count fingers, and with a little difficulty could distinguish the flame of a candle, with the injured eye. The amblyopia appeared to be due to the opacity of the lens. The wound had not healed over. There was some little ciliary injection of the nasal border, but the eye appeared to be steadily quieting down, and there was no sympathetic trouble of the other eye.

Three days after this he thought that he had caught cold in the injured eye. The bulb became deeply injected, but there was no involvement of the other as yet. In fact, it registered an accommodation of one-fourth. A week from this date (five and a half weeks after the reception of the injury) he complained of tenderness of the sound eye when he looked at anything for any length of time, and that strong light, although not painful, was disagreeable to him. Careful ophthalmoscopic examination revealed nothing abnormal in the fundus; his vision was normal $\frac{20}{20}$, and his accommodation was one-fourth, as before.

Enucleation of the injured bulb was again urged, and was now consented to. It was done with every prospect of success, as there was only the slightest flushing of the sound eye, and the accommodation was perfect. A week after, although the pupil of the eye was fully and equally dilated, the iris was discolored, and there was much circumcorneal injection. Iridocyclitis was set up; and as to subjective symptoms, he complained that everything appeared to him to be shrouded in mist.

The vision four days after this had sunk to $\frac{3}{10}$. From this time his vision passed through several degrees of acuity, but never improved beyond $\frac{1}{6}$. At the present date, five months after the enucleation, the eye still presents an irritable appearance; there is a slight ciliary zone; the pupil is fixed at half dilatation, of a slightly oval contour, the long axis vertical. The iris is discolored of a dirty, dull green color, while loops of new proliferations are seen fringing the circle of the uvea; new formations have also sprung from the anterior capsule of the lens, adding still more to the dulness of the parts. Now, these are certainly sad details to enumerate; and yet everything was done "in the nick of time" to save the uninjured eye (at least during the secondary period).

The great error was in the patient's declining the operation when first seen. Had he accepted it then, he would now have one good eye, instead of being blind. Granting that the vision of the injured bulb rose to quantitative perception, it was then at its maximum, and, from the nature of the injury and its severity, with its inevitable choroiditis and resulting effusions, the chronic involvement of the ciliary body in the tedious exudations and proliferations certain to drag their slow length along, it was impossible for the eye ever to be of a particle of use, but it was highly possible for it to be a most dangerous possession. And so it proved, in spite of the most anxious watching on the part of the surgeon, and the removal of the eye to all appearance as a measure anticipatory of coming evil.

Dr. H. H. Smith, in connection with the remarks of Dr. Hall, wished to call the attention of the Society to the very marked and happy results of the application of electricity in a case of blindness. A child 9 years

old suffered, eighteen months since, from bad scarlatina, followed by otorrhœa. About two months since he was accidentally found to be perfectly blind of the left eye, being unable to distinguish any light. An examination by Dr. Franklin D. Castle, with the ophthalmoscope, revealed anæmia and atrophy of the retina. The boy at this time was not aware of any light or impression made by the ophthalmoscope. The case being placed in Dr. Castle's charge, it was agreed to try the effects of electricity, applied through the eyeball by connecting the negative pole of the battery with an eye-cup of water in contact with the ball, placing the positive pole on the nape of the neck; and to combine with this the chalybeates, etc. In a day or two afterwards the "continued current" was thus applied for fifteen minutes, at the end of which time the patient recognized various objects, and now can read ½-inch type for half an hour daily, the right eye being closely bandaged. The case continued to improve, and there was reason to anticipate a permanent cure. Dr. Smith was not aware of any other marked case like this, and therefore presented it to the Society.

In reference to the case narrated by Professor Smith, Dr. HALL asked the exact nature of the lesion. If it were a case of anæmia or anæsthetic condition of the optic nerve, he could well understand that the electric stimulus might furnish "a fillip" to the halting function. He had a case under treatment in which the nerve was blanched; the field of vision contracted in its periphery; the amount of vision being $\frac{1}{200}$ for the right eye, and for the left $\frac{4}{40}$.

The man was 55 years of age, an engineer; had noticed dimness of vision of the left eye for four months. It had occurred "all at once," preceded by "flashes of light" for a day or two previous. He had no headache, nor any pain in the eye. The right eye was good at that time; two months later there was sudden diminution of vision.

He considered himself temperate. The steam and glare of his occupation caused the disease, in his own opinion.

The only appearance on ophthalmoscopic examination was a slight blanching of the papillæ.

The treatment at first pursued was moderate local depletion by the Heurteloup leech, repeated at stated intervals, and an alterative course of corrosive sublimate and potassium, followed by a tonic course of iron, quinine, and strychnia. Suffice it to say that the improvement, if it took place at all, was hard to perceive. He did not see the patient for several months, during an absence in Europe; but on his return it was found that vision of the left eye was quantitative, whilst that of the right eye was $\frac{2}{40}$. The patient was almost discouraged, and his surgeon quite so. He had "rung all the changes" of treatment, and it was feared that the case must be pronounced incurable. Just then Dr. H. happened upon Professor Nägel of Tübingen's brochure on "Strychnia as a Remedial Agent in Amaurosis," and shortly after the papers of Professor Chisolm, of Baltimore, upon the subject of subcutaneous injections of strychnia. He therefore resolved, as a "*dernier ressort*," to put this method to the test. He began, as recommended by Chisolm, with $\frac{1}{40}$ of a grain of sulphate of strychnia, on the 19th of November, 1872. This was continued each morning, increasing the strength by a few minims each day. On the 7th of December, after using ¼ of a grain of strychnia for several days, the patient said that "he saw the numbers of houses across the street quite plainly;" he also felt the effect of the previous morning's injection quite severely,—such as rigidity about the jaws and muscles of the neck; and here Dr. H.'s experience seemed to corroborate that of the other observers,—that but slight effect was produced until one mounted up among the ¼-grain doses.

22d of January, 1873, the patient was taking ⅓ of a grain by injection in the morning, and a pill of $\frac{1}{30}$ of a grain by the mouth in the evening.

He then read 3½ of Snellen's types with a +12 glass slowly.

4th of February, 1873.—Has been taking ½-grain injections in the morning, with the usual night dose ($\frac{1}{30}$ gr.) for a day or two. He now reads No. 3 of Snellen with +12 (= to ordinary newspaper type).

The ½-grain injections were continued daily, and on the 3d of March he stated that he saw the *North American* newspaper better than he had done for three months previous, and that his distant sight was better also, although the snow on the ground was unfavorable for clear vision. A member of his family also said that his vision was "fifty per cent. better."

REVIEWS AND BOOK NOTICES.

THE MEDICAL AND SURGICAL HISTORY OF THE WAR OF THE REBELLION (1861–1865). Prepared, in Accordance with Acts of Congress, under the Direction of Surgeon-General JOSEPH K. BARNES, United States Army. 2 vols. 4to, pp. 1134 and 819. Washington, Government Printing-Office, 1870.

We think that a just pride will be felt by the American medical profession, and indeed by our countrymen generally, in these admirable volumes. They afford a singular proof of the intellectual activity which could, amid all the horrors of civil war, coming suddenly upon a nation "quiet and secure," as the Scripture has it, not only grapple with the great issues of the contest, raise men, money, and supplies, but develop a medical organization and a hospital system which is at the present time a model for such services throughout the civilized world; and, beyond all this, could utilize the fearful experiences of the struggle so as to crown its results with a contribution to science such as that we have now to notice.

Nor does it seem as if any one acquainted with the early history of the war, and especially of the Army Medical Department, could fail to be reminded, by these volumes, of the valuable services rendered during his brief career as Surgeon-General by Dr. William A. Hammond. His harsh dismissal, on grounds partly technical and partly personal, but in no way touching his integrity, took the work he had so ably begun out of his hands. It had, however, acquired a definiteness and a momentum which were fully recognized by his successor, the present chief of the army medical service, who has shown not only zeal and activity, but enlightened judgment, in his administration.

The first volume opens with a prefatory note, by Surgeon-General Barnes, briefly sketching the history and objects of the work. Following this is an introduction, by Surgeon J. J. Woodward, to whom the medical portion of the task was assigned. We learn from this that the basis of the statistical tables is slightly modified from that adopted by Dr. Farr, the English statician, and is as follows:

"Class I. Zymotic Diseases.—Order 1, Miasmatic. Order 2, Enthetic. Order 3, Dietic.

"Class II. Constitutional Diseases.—Order 1, Diathetic. Order 2, Tubercular.

"Class III. Parasitic Diseases.

"Class IV. Local Diseases.—Order 1, Of the Nervous System. Order 2, Of the Eye. Order 3, Of the Ear. Order 4, Of the Organs of Circulation. Order 5, Of the Respiratory Organs. Order 6, Of the Digestive Organs. Order 7, Of the Urinary and Genital Organs. Order 8,

Of the Bones and Joints. Order 9, Of the Integumentary System.

"Class V. Wounds, Accidents, and Injuries.—Order 1, Wounds, Accidents, and Injuries. Order 2, Homicide. Order 3, Suicide. Order 4, Execution of Sentence."

The tables arranged on this plan are based on the Monthly Sick Reports made to the Department, and are arranged in years corresponding with the fiscal years, which end on the 30th of June. The statistics of the white troops embrace officers as well as enlisted men; those of the colored troops include the enlisted men only, the officers being all white. They are derived immediately from a comparison of data obtained from three sources,—viz., the Adjutant-General's office, the Quartermaster-General's office, and the Surgeon-General's office; and the amount of labor involved is scarcely conceivable. *Seven hundred and twenty-six* pages are occupied by these tables, which do not include, of course, the killed in battle.

Surgeon Woodward's explanatory introduction—which, by the way, contains a brief but interesting sketch of the development of the system of post, regimental, division, and general hospitals—should be carefully read and weighed by all who would consult these most valuable statistics.

The appendix to this part, occupying three hundred and sixty-five pages, consists of Reports of Medical Directors, and other documents, constituting a very important contribution to the history of the war.

In the second, or surgical volume, prepared by Surgeon George A. Otis, we have first an explanatory introduction, containing much matter of interest. We note a sad but honorable record of medical officers killed and wounded in the discharge of their duty. Nineteen lost their lives in battle; thirteen were killed by partisan troops, guerillas, or by rioters; eight died in consequence of wounds, and nine of accidents; while seventy-three were wounded in action.

A chronological summary of engagements and battles, with the number of Union troops engaged, and of killed, wounded, and missing on both sides, covering one hundred and six pages, leads to the scientific portion of this volume, which is devoted to the discussion of wounds and injuries of the head, chest, and spine. Wounds of the abdomen and pelvis will be treated of in the next volume.

We greatly regret that our limited space wholly precludes any attempt at an analysis of the matter contained in these pages, which are amply and admirably illustrated. Surgeons will find in them a mine of information worthy of the closest study and reflection.

GLEANINGS FROM OUR EXCHANGES.

Insanity.—We take the following from a lecture by Dr. C. B. Radcliffe, in the *British Medical Journal* for April 5:

"That state of mind to which is given the name of melancholy is so common among lunatics, that melancholy and insanity have been used as mutually convertible terms. The anatomy of melancholy, to go no further, is a treatise on insanity. In some cases, of course, this state of mind is not so obvious as in others, and it may be difficult to detect it if the patient be reticent. In the more aggravated cases there is no such difficulty, the patient often sitting hour after hour, or day after day, motionless, with clasped hands and woebegone features, or else, driven past endurance by feelings of anguish and despair, continually moving about, moaning or wailing, wringing his hands, praying for death, or even seeking it, too often successfully, at his own hands. As a rule, this state of mind would seem to be the very reverse of that which shows itself in inordinate self-esteem, the patient often believing himself to be thoroughly bad and wicked in every way, with a dreadful doom in store for him both here and hereafter. And the more marked delusions in association with melancholy are in conformity with this idea. I know, for example, a miserable man, long a victim to deep melancholy without delusion, whose delusion now is that he is a murderer, condemned and left for immediate execution, who will not look out of window lest he should see the gallows, and who, whenever the handle of his door turns, expects the executioner. And the cases are legion of those who think that they have committed the unpardonable sin, for which their inevitable doom is everlasting destruction. It would also seem that this terrible self-depreciation may lead to another kind of delusion, the very opposite of that to which inordinate self-esteem would seem to lead in some cases,—namely, to a loss of personal identity, in which the idea of self is lost, as it is lost in lycanthropy. At all events, I know of one case in which there were true fits of lycanthropy, or rather cynanthropy, where the settled melancholy, which was the predominant state between the fits, had its origin in what may be spoken of as the *worm-doctrine* of human nature, and in the miserable forebodings as to the future to which it led. But, be the relation of this, or any form of delusion, to melancholy what it may, the facts remain not only that melancholy is a morbid feature in insanity, but that melancholy, more or less deep, without delusion, must have assigned to it a very prominent position among the symptoms of incipient insanity.

"There are, no doubt, many variations and many combinations in the symptoms of incipient insanity. Sometimes one or two of the symptoms only are present, to the exclusion of the rest. If all are present,—an almost inconceivable case,—then there would be a state of intense self-conceit without actual delusion; a state of moroseness and misanthropy without actual delusion; a state marked by great mistrust and suspicion, without actual delusion; a state of uncontrollable impulsiveness without actual delusion; a state of melancholy without actual delusion; a warped state of the intellect without actual delusion, irregularity of fancy showing itself in illusions and hallucinations; and, lastly, a tendency to delirious excitement. In actual insanity one or more of these several morbid mental conditions is always present, the change which has happened consisting only in the addition of some actual delusion, which delusion very often, to say the least, may be looked upon as the natural result of the exaggeration of the morbid mental condition most closely associated with it."

Myotomy before Cataract Operations.—Mr. Edwin Chesshire, Senior Surgeon to the Birmingham and Midland Eye Hospital, advocates, in the *British Medical Journal* for April 5, section of the orbicular muscle and integument of the outer canthus as a preliminary to the extraction of cataract.

The advantages he claims for this are "more extensive exposure of the globe, which enables the operator to manipulate his instruments, and to make his section through the cornea with greater ease. And the spasmodic contraction of the orbicular muscle being overcome, the operator is left to complete his operation at his leisure; while all risk of sudden protrusion of the lens, followed as it sometimes is by prolapse of the iris and escape of the vitreous, is almost entirely avoided; and the contraction of the lids on the globe, which is sometimes a troublesome symptom in the after-treatment of cataract-extraction, is prevented.

"With division of the orbicular muscle, the wire speculum, which greatly facilitates each step of the operation, may be used without injury or annoyance to the patient. No sutures are required, as the divided surfaces readily unite, and scarcely leave a trace behind them. All that is necessary to be done is to keep the eyelids nicely in apposition for a few days after the operation by means of strips of court-plaster. All bandages and other coverings after extraction are to my mind objectionable, as it is important to have the fullest opportunity of examining the appearance of the lids without disturbing the patient by the removal of external appliances. Moreover, the support afforded by the lids to the corneal flap, when nicely kept in position by strips of court-plaster, is very agreeable to the patient. Spasm may be brought on, and the partially-healed corneal flap may be opened, by the removal of bandages, wool, etc., which may have become adherent to the lids.

"The operation is done as follows. A wire speculum is placed between the lids, to enable the operator to make his section through the muscle and integument at the external canthus with precision and ease. I have made no allusion to the mode of extracting, as the plan I propose is equally applicable to all extractions. I never use chloroform or ether in extraction, as the sickness which frequently follows their administration far outweighs any advantage that may otherwise result from the use of anæsthetics during the operation; and with the orbicular section, the globe being more under control, they are still less required. Where great neatness is desired, the section may be made subcutaneously."

Acute Bronchocele (*British Medical Journal;* from the *Archiv der Heilkunde*, vol. xiv. No. 6).—Dr. Ludwig (of Pontresina) describes the case of a gentleman who, after suffering from violent paroxysms of cough for some days, was suddenly seized with a swelling on the front of the neck, which impeded respiration. There was found to be an elastic swelling extending downwards from four centimetres below the middle of the thyroid cartilage nearly to the sternum, and to the sterno-mastoid muscle on each side. In the course of a few hours, it increased to the size of a child's head; the dyspnœa became more intense, and deglutition was difficult. There was no pulsation in the tumor. Soon, however, it began to diminish; and the next day it had entirely disappeared. Ludwig regards the case as one of acute hyperæmia of the thyroid body, but cannot assign a cause.

On Temperature in Phthisis.—In an inaugural thesis published on the above subject by Dr. Bilhaut, the author puts down the following, among other conclusions. From the outset of the disease the temperature rises; towards the end of the disease there is often a marked decrease of temperature; diarrhœa and abundant hæmoptysis produce a fall of temperature; differences of temperature show the gravity of the disease; slow asphyxia and inanition induce a fall of temperature towards the approach of death; the tracings in cheesy pneumonia seem to be more regular as regards vesperal exacerbations and morning remissions than the tracings in tuberculosis; the complications of the disease modify the form of the tracings.

MISCELLANY.

Leprosy in the Sandwich Islands.—The Honolulu *Gazette* says, "Dr. Trousseau and Hon. S. G. Wilder, of the Board of Health, visited the Leper Hospital at Kalaupapa, on Molokai, on Wednesday and Thursday of last week. They found the settlement numbered over 600 persons, of whom about 120 were the natives who lived in the village prior to its selection as a hospital site, who, as owners of the land, prefer to remain on it. There are over 400 lepers, and about 100 relatives, who have gone there self-banished rather than be separated from their kin. The patients, gathered there from every island of the group, were as contented as could be expected. No complaint was made by any one, and, in answer to inquiries, all said they had an abundance of food and everything they wanted. Few realize the magnitude of this work. The plague is extending, and, with all the vigilance of the authorities to check it by isolating every new case, it is rapidly spreading, chiefly among the young, who inherit it from their parents. The very worst cases are boys and girls; and to establish and carry out the rule that every child tainted with the disease must be torn from its parents and banished for life among strangers and lepers, seems cruel. Yet this is now being done every month with natives."

At the recent meeting of the British General Medical Council on Education and Registration, the name of Dr. Matthew Bass Smith was ordered to be erased from the *Register*, for "infamous conduct in a professional respect," in seducing a female patient.

Another charge, that a surgeon had "stated or insinuated, or used language from which the inference might be drawn," that he had committed adultery with a married patient of his, was decided not to be sustained by the evidence.

"The case of James Mawhinney, supposed to be a registered person, convicted of theft at Stirling, was deferred for legal evidence of identity."

The name of Dr. Frederick Henry Morris, erased from the *Register*, "in consequence of his conviction on an alleged charge of indecent assault," in 1871, was ordered to be restored.

[If such cases exist in this country, as they very probably do, there is no central authority to take cognizance of them.—Ed.]

Inhumanity.—An inquest was lately held in London respecting the death of Elizabeth Jackson, aged 18, a domestic servant. Her mistress, learning that she was feverish, told her she had better go, as she did not want anybody in such a state there. The deceased then went to a Mrs. Foley, who, however, finding she was feverish, also turned her away. The deceased was provided with a bed by a Mrs. Henley, but was taken out and placed on the stones when it transpired that she had a fever. A police constable, finding her insensible on the stones, had her removed to the hospital, where she died from inflammation of the brain. The coroner said that he had never had a worse case of inhumanity before him. The women might have taken the deceased to the infirmary instead of turning her into the streets. The jury returned a verdict in accordance with the medical evidence.

Powerful Medicines.—A homœopathic practitioner writes to one of their periodicals that he has a score of

times known medicine prescribed by him to break the glasses in which it was mixed, and that other physicians of the same faith had found it a very common thing. He says, "I have had glass broken by belladonna 30th, mercurius solubilis 6th and 12th, pulsatilla 30th, and also by colocynth 2d, but never by any potency lower."

It certainly seems like heroic practice to put such articles (*if* the story be true) into the human stomach.

PROFESSOR TYNDALL, during his recent scientific lecturing tour in the United States, delivered in all thirty-five lectures, at which his receipts aggregated $23,100. After paying expenses, a fund of over $13,000 remained; and this, before leaving for Europe, he placed in the hands of a committee, who are authorized "to expend the interest in aid of students who devote themselves to original research." The committee are Professor Joseph Henry, of the Smithsonian Institute; Professor E. L. Youmans, of Yale College; and General Hector Tyndale, of Philadelphia.

THE Association of American Medical Editors will meet at St. Louis on Monday evening, May 5, at 8 o'clock.

The American Medical Association begins its session the next day. We have not, as yet, heard whether or not the attendance is likely to be large.

THE Chief of the Medical Division of the Pension Office is about to make a pretty thorough reorganization of his corps of examining surgeons throughout the country, since a number of them, it is alleged, are not so prompt and careful in their duties as it is desirable that they should be.

THE carcass of a horse was dissected in Edinburgh a few weeks since with the result of extracting from the stomach a large dust-ball as hard as stone, about twenty-three inches in circumference, and weighing eight pounds. The animal had been fed on mill-dust.

THE Indianapolis *Journal* complains that, in making post-mortem examinations, the doctors of that place use a wood-saw, a butter-knife, and an axe.

A FRENCH physician has discovered that the death-rate in Paris has increased in proportion as cravats have decreased in size.

BARON JUSTUS LIEBIG.—The death of this eminent authority in chemistry and physiology, at the age of 70, is announced.

THE directors of the Bank of England have voted £1000 in aid of the London Hospital Extension Fund.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending April 19, 1873, were 357; 175 adults, and 182 minors. 11 were of bodies brought from the country; making the mortality of the city 346. Among the assigned causes of death were:

Consumption of the Lungs	55
Other Diseases of the Respiratory Organs	63
Diseases of the Circulatory Apparatus	16
Diseases of the Brain and Nervous System	60
Diseases of the Digestive Apparatus	28
Zymotic Diseases (9 from Scarlet Fever)	30
Typhoid Fever	5
Casualties	11
Cancer	9
Tumors	2
Syphilis	3
Exposure	1
Debility (including "Inanition" and "Marasmus")	24
Still-born	23
Old Age	11

(The interments reported for the week ending April 20, 1872, were 361.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER. Max.	Min.	BAROMETER. (2 P.M.)
April 13	52.0°	43.0°	29.99 in.
" 14	60.0	49.0	29.96 in.
" 15	59.0	49.5	30.06 in.
" 16	56.0	46.0	30.26 in. (Rain.)
" 17	47.0	39.0	29.87 in. (Rain.)
" 18	58.0	43.0	29.80 in.
" 19	58.0	49.0	29.86 in. (Showers.)

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 15, 1873, TO APRIL 21, 1873, INCLUSIVE.

MCLAREN, A. N., SURGEON.—Granted leave of absence for sixty days, to take effect from May 1, 1873. S. O. 14, Military Division of the Atlantic, April 16, 1873.

By S. O. 82, War Department, A. G. O., April 18, 1873, the following changes are made:

The following officers are relieved from their present duties, and ordered to report in person to the Commanding Generals of the Departments to which they are respectively transferred, for assignment to duty:

SMITH, ANDREW K., SURGEON, from the Department of the South to that of the Missouri.

GRAY, CHARLES C., SURGEON, from the Department of the East to that of Texas.

FRYER, BLENCOWE E., SURGEON, from the Department of the Missouri to that of the East.

WEEDS, JAMES F., SURGEON, from the Department of the South to that of Dakota.

MIDDLETON, J. V. D., ASSISTANT-SURGEON, from the Department of the Gulf to that of Dakota.

WOODHULL, ALFRED A., ASSISTANT-SURGEON, relieved from duty in the Department of the Missouri, to proceed to Baltimore, Md., and report by letter thence to the Surgeon-General.

The following officers are relieved from duty in the Departments set opposite their respective names, will proceed to New York City, and report thence by letter to the Surgeon-General:

GREENLEAF, CHARLES R., ASSISTANT-SURGEON, Department of the Columbia; AZPELL, THOMAS F., ASSISTANT-SURGEON, Department of California; BREWER, JOHN W., ASSISTANT-SURGEON, Department of the Missouri; KOERPER, EGON A., ASSISTANT-SURGEON, and PATZKI, JULIUS H., ASSISTANT-SURGEON, Department of Texas.

WHITE, R. H., ASSISTANT-SURGEON.—Relieved from duty at Mobile, Alabama, and to comply with S. O. 74, c. s., A. G. O.

CORSON, J. K., ASSISTANT-SURGEON.—Assigned to duty at Mobile, Alabama.

SATURDAY, MAY 3, 1873.

LECTURE X.

TUMORS OF THE NASAL PASSAGES.

TUMORS are frequently developed in the nasal passages, and in their communicating cavities and sinuses. They originate from the mucous membrane, for the most part, but sometimes from the perichondrium or the periosteum.

The symptoms of a tumor in the nasal passages are, more or less obstruction to nasal respiration, sometimes hemorrhage, sometimes deformity; and these symptoms become pronounced so gradually that professional attention is not often attracted to them until the tumor has gained some considerable size. They are rarely attended with pain; but there is an annoying sensation of stuffing up of the nostrils, or obstruction at the posterior nares, more marked at irregular intervals, most frequently during change of moisture and temperature. These sensations induce sneezing, hawking, nasal excretions, and a frequent desire to use the handkerchief. Sometimes these symptoms resemble those of asthma so closely as to lead an unobservant medical attendant to the diagnosis of that affection. The sense of smell becomes impaired, and diminishes in acuteness with the growth of the tumor. If the tumor encroaches upon the outlet of the nasal duct, epiphora may be produced. If it encroaches upon the pharyngeal orifice of the Eustachian tube, more or less impairment of hearing may be produced. If it obstructs the outlet of the maxillary sinus, the development there of a cystic or other growth may be induced.

Tumors are apt to be attended with chronic catarrh, and there is a more or less constant discharge of mucus, or of mucus and pus, not infrequently mingled with blood, if the tumor is vascular and its vessels delicate. Osseous, carcinomatous, and fibroid tumors are often accompanied by the more familiar myxoma, or gelatinoid polypus; and, in some instances, the existence of the more serious trouble is not detected until the removal of the minor ones. Where the tumor is large and of soft consistence, portions become detached, and are expelled by sneezing or by blowing the nostrils.

The variety of tumor most frequently developed in the nasal passages is the myxoma, or gelatinoid polypus. It originates in an enlargement of the acinous glands of the mucous membrane, the mucous membrane itself becoming hypertrophied and elongated, so that a narrow pedicle is thus formed; and the tumor acquires somewhat the configuration of an oyster, of a dull, dingy-whitish color. Its consistence is soft, its surface smooth, and it hangs downward into the nostril or backward into the pharynx, being attached to one of the turbinated bones. It varies in size from the bulk of a small bean, to a magnitude sufficient to obstruct respiration completely, or to distend the nose out of shape. It is occasionally solitary, but more frequently multiple.

The fibroma is a less frequent variety of tumor, red in color, of firmer consistence than the myxoma, more irregular in contour, and usually attached by a broad base, though sometimes by a pedicle. It is generally single, and takes its origin in the submucous connective tissue, or in the perichondrium or periosteum, as the case may be. It is liable to develop in every direction, protruding into the pharynx, and sending out prolongations into the neighboring sinuses, where its subsequent development produces a characteristic deformity of visage denominated frog-face.

Adenomata occur still less frequently. They are developed from the glands of the mucous membrane, and may attain great size, and extend to the smallest anfractuosities of the nasal passages and adjacent sinuses.

Neuromata have occasionally been encountered in the nasal passages.

Epitheliomata and encephaloid tumors sometimes involve the nasal passages, but usually originate outside of them. The disease eventually involves all the adjacent tissues.

Enchondromata have been found developed in connection with the nasal septum.

Osteomata are occasionally developed in the nasal passages. They are not mere exostoses or osseous sarcomata, but true bony tumors, of cancellated or of compact tissue, wholly unconnected with the normal bone, and developed primarily in the submucous or fibrous tissue. The pressure of the tumor upon the normal bony structure may lead to its absorption, but the tumor remains essentially a distinct growth. These tumors increase slowly in size, producing great deformity; their pressure upon the nerve-tracts eventually exciting intense pain, which may involve all the branches of the fifth pair. When it has acquired considerable bulk, the tumor may be detected by the finger in the nostril, or may become visible exteriorly. At first it is covered by mucous membrane, but this gradually gives way, and the osseous nature of the tumor can be detected by the touch.

The operative removal of nasal tumors is frequently indicated. They are not amenable, as a rule, to any other treatment, though there are some instances recorded of their destruction by astringents, cauterization, and electrolysis.

The myxoma and the pedunculated fibroma are usually removed by torsion with slender but strong forceps, passed well over the pedicle of the growth

so as to tear it from its attachment. If several tumors are present, it is considered best to remove them all at one sitting, if this be possible. The blood lost in these operations is usually washed out by syringing; if the hemorrhage is at all profuse, astringents and ice are applied locally; and if these fail, the nostrils are plugged back and front by the nasal tampon. Sometimes these tumors are removable by the wire snare, a less painful operation than torsion, and less apt to tear away portions of the turbinated bones. The galvano-caustic loop is also used for the same purpose, and has the advantage of being productive of less hemorrhage.

When the tumor is deeply situated, or hangs into the pharynx, it is often encircled by a wire loop passed through the nostrils; the loop is then pushed up behind the growth as high as possible, and a suitable canula slid over the free ends of the wire to the growth, which is then compressed by traction upon the wire. Sometimes the tumor is merely strangulated in this way, and allowed to slough off; under which circumstances it is to be secured by a thread reaching outside of the mouth and confined to the ear, so as to prevent the tumor from falling off, at an inopportune moment, into or upon the larynx.

The tendency to repullulation of tumors removed from the nasal passages is restrained by the local application of astringents and caustics.

Tumors with extensive attachments sometimes require access to be made to them by external incision through the nose or upper jaw, various operations for which have been performed with such modifications as are suggested by the nature of the case.

Osseous tumors are removed by gaining complete access to the body of the tumor from the outside, when, if cancellated tissue predominates, it may be crushed with the forceps and removed in fragments. The compact or eburnated osseous tumor cannot be crushed in the forceps, or even cut with the chisel. Free access must be had to its largest portion, and all constrictions removed, whether soft or bony. It is then seized with strong forceps and easily dislodged by traction from one side to the other, coming away in mass, or in masses. The bones have frequently to be resected in part, and turned aside, in order to get access to these tumors.

Electrolysis has been successfully applied by Nélaton, Bruns, and others, to produce decomposition and absorption of extensive fibroid tumors; and it has been claimed that, in some of these successful cases, any ordinary surgical procedure would have compromised the life of the patient, on account of the size of the tumor, its location, and the nature of its attachments.

A MOVEMENT is on foot to establish a medical club in Paris,—the *Cercle Médical*. It is to include in its membership Parisian and provincial physicians, and students of medicine. A library is to be one of its chief features. The annual contribution will be one hundred francs for Parisian and twenty francs for provincial doctors, and sixty francs for students.

ORIGINAL COMMUNICATIONS.

ON THE ACTION OF DIGITALIS UPON THE CIRCULATION.

BY DR. H. C. WOOD, JR.

THE action of digitalis upon the heart of the frog was, I believe, first investigated by M. Vulpian,* who has been followed by numerous observers, among whom may be mentioned W. Dybkowsky and E. Pelikan,† A. B. Meyer,‡ Legros and Legroux,§ Claude Bernard,§ Rudolf Boehm,‖ Homolle,¶ Gourvat,** Fothergill,†† Fagge, and Stevenson.‡‡

The statements of these investigators agree in all essential points. One or two of them have occasionally noted a primary brief acceleration of the heart's action; but the rarity of its occurrence shows that it has been probably produced by some extraneous unnoted influence.

The first distinctive action of the drug is a marked lessening of the number of cardiac beats per minute, due to a prolongation of the diastole, which may be complete, but is more generally divided by an abortive attempt at ventricular contraction. The systole is abnormally energetic, so that the ventricles become white as the last drop of blood is squeezed out of them. As the action of the drug becomes more intense, the rhythm of the heart is very much affected, the ventricle and auricle no longer beating in accord. At the same time the diastole generally becomes imperfect, one portion of the ventricle maintaining its systolic spasm, while the rest dilates. Thus the extreme apex may remain hard and white during the diastole, and even hernial protrusions of the ventricle may occur. Finally, the heart is arrested in systole; and as the muscle so hardens, of course all its power of responding to electrical or other excitants is lost.

In some rare instances, instead of the above series of phenomena, the diastolic periods throughout are prolonged and quiet, and after several periods of relaxation, lasting for ten or twenty seconds, final diastolic arrest may occur.

As both Boehm (*op. cit.*, p. 163) and Dybkowsky and Pelikan (*loc. cit.*) have found that the slowing of the heart's beat, the increased energy of contraction, the irregularity and final systolic arrest, are produced by digitalis after division of the vagi and destruction of the spinal cord, and as both Ackermann §§ and Boehm have found that the paralyzing of the peripheral ends of the vagi by atropia does not prevent the phenomena just alluded to, it is evident that the drug acts directly upon the heart-muscle itself, a conclusion which is confirmed by Eulenberg and Ehrenhaus,‖‖ who found that digitalis, when

locally applied, acts at once upon the heart. On the other hand, the inhibitory activity of the peripheral ends of the pneumogastrics is without doubt increased by the drug. There is no stage in which stimulation of the vagi does not cause diastolic arrest. Indeed, Dybkowsky and Pelikan have seen galvanization of the nerves produce such relaxation in the auricles after the ventricles had already become permanently contracted. Further, Boehm has found that a stimulation of the pneumogastrics which is insufficient to make itself felt before poisoning will, after the exhibition of digitalis, cause diastolic arrest lasting for many minutes.

It appears, therefore, that the peripheral cardiac inhibitory apparatus shares in the stimulant action of digitalis; and, as Boehm has found that diastolic arrest never takes place in frogs poisoned with the drug, after section of the vagi, it is probable that this rare mode of death is really due to super-excitation of the inhibitory cardiac nerves.

Rudolf Boehm (*op. cit.*, p. 170) has investigated the influence of digitalis upon the working power of the heart when freed from all connection with the central nervous system. By using the method of Ludwig and Coats, he obtained as a constant result that the amount of work done was increased by small doses of digitalis; that, after large doses, a similar increase was followed in a short time by very great diminution in the expenditure of power by the heart, a diminution apparently due to imperfect diastole and consequent non-admission of serum into the viscus.

The elaborate experiments of L. Traube* upon warm-blooded animals showed that in dogs moderate doses of digitalis produce increased arterial pressure, with lowering of the rate of the cardiac pulsation. When toxic doses were used, these phenomena were followed by increase of the pulse-frequency and fall of the arterial pressure, which did not commence at the same time, since the maximum pressure was not reached until the pulse had risen above the original, normal point.

Boehm (*loc. cit.*) has confirmed these results, and has also noticed a very marked dicrotic pulse, evidently due to an abortive ventricular contraction during diastole, precisely as occurs in frogs.

The experiments of Brunton (*loc. cit.*) and of Gourvat (*loc. cit.*) also are in accord with those of Traube; so that it may be considered proven that in mammals moderate doses of digitalis produce rise of arterial pressure with diminished pulse-rate.

Prof. L. Traube has found that, after section of the vagi, digitalis is in warm-blooded animals, with rare exceptions, incapable of reducing the pulse-rate, and, contrariwise, that when the pulse-frequency has been reduced by the drug, section of the nerves causes an immediate and very marked rise in the rate of pulsation. I believe Boehm† has experimentally confirmed this; and in the single experiment of Gourvat a similar result was attained.

The conclusion would seem to be inevitable, that in mammals the reduction in the pulse produced by digitalis is directly or indirectly owing to an excitation of the peripheral inhibitory apparatus. The occasional reduction of the pulse-rate after section of the pneumogastrics shows, however, either that the inhibitory nerves in some animals find another path than the pneumogastrics, or else that there is an additional—sometimes inoperative, sometimes efficient—cause of the reduction of the pulse-rate. As it has been shown that digitalis is capable of slowing the beat of the isolated heart of the frog, it would appear probable that it may exert a similar influence at times, in mammals, upon the cardiac muscle or its contained ganglia.

Although digitalis does increase the muscular energy of the heart, it seems scarcely possible that the enormous rise of pressure produced by it can be owing to this alone. This *a priori* reasoning has received experimental confirmation from Malan,‡ Fothergill (*loc. cit.*), Gourvat (*loc. cit.*), and Ackermann.§ The first three of these investigators have found that the arterioles of the frog's web undergo very decided contraction after the systemic use of digitalis; and Ackermann states that if the abdomen of a rabbit be opened so as to expose the arteries of the mesentery, a very marked contraction, even to the partial obliteration of the lumen of the vessels, can be readily seen to follow the exhibition of digitalis.

According to Boehm, Traube found that if the spine be divided, digitalis is powerless to increase the arterial pressure, although lessening, as usual, the pulse-rate. The same authority also states that Bezold has seen an excessive fall of the arterial pressure ensue immediately upon the division of the spinal cord in an animal under the influence of digitalis. Further, in his own experiments, Boehm has attained similar results, or, in other words, has found that after separation of the small vessels from the vaso-motor nerve-centre, digitalis does not increase arterial pressure.

These experiments would appear to prove that digitalis acts upon the vessels by stimulating the vaso-motor centres in the base of the brain; but they have been contradicted by Ackermann (*op. cit.*, p. 397), who states that he has many times cut the spinal cord, and without exception found a very marked rise of arterial pressure follow the injection of digitalis. Unfortunately, none of these experiments have, that I am aware of, been published in detail, and it is therefore impossible to analyze or reconcile them. It must be considered undetermined whether Professor Ackermann is or is not correct in asserting that digitalis acts directly upon the peripheral vessels themselves.

From the evidence which has been brought forward, it may be considered as definitely proven that in mammals digitalis in therapeutic doses is a powerful stimulant to the circulatory system.

The following proposition expresses our present knowledge, and probably is very close to the truth:

Digitalis in moderate doses stimulates the mus-

* Gesammelte Beiträge zur Pathologie und Physiologie, Bd. i., Berlin, 1871.

† His language is such as to leave the point somewhat doubtful. (*Op. cit.*, pp. 188, 189.)

‡ Quoted by Fothergill (*op. cit.*).

§ Ueber die Wirkungen der Digitalis: Volkmann's Sammlung Klinischer Vorträge, No. 48, Leipsic, 1872.

culo-motor portion of the heart (probably its contained ganglia), increases the activity of the inhibitory apparatus, and causes contraction of the arterioles. As a consequence of the first action, the cardiac beats become much stronger; as the result of the last, there is narrowing of the blood-paths, and to the passage of the vital fluid an increased resistance, which, acting on the already excited inhibitory system, aids in the slowing of the pulse. Toxic doses of digitalis paralyze or weaken, more or less completely, each of the three systems, and cause rapidity of the pulse and falling of the arterial pressure.

According to my own experience, decided therapeutic doses of digitalis, in man as in other mammals, produce great reduction and sometimes dicrotism of the pulse, and increase the size and force of the wave; at the same time the arterial tension is augmented. Poisonous doses induce, after a time, increase of the pulse-rate, with smallness and weakness of the wave and lowered arterial pressure.

Sphygmographic studies of the effect of digitalis upon persons suffering from various acute and chronic diseases have been made by M. Legroux, M. Bordier,* Constantine Paul,† and Paul Lorrain.‡ The problems offered by these gentlemen are so complex as to render a detailed study almost impossible; but, as a whole, their tracings seem to confirm my personal experience. Paul Lorrain calls attention to the fact that when the drug has reduced the pulse-rate very greatly, a second abortive systole can, on auscultation, sometimes be heard occurring during the long diastole, and some of his sphygmographic tracings are markedly dicrotic. It is evident that in man the second systolic movement occurs precisely as in animals; and it seems very certain that the proposition framed for the lower mammals applies also to man.

When the pulse has been reduced by digitalis to forty or fifty a minute, the change from the recumbent to the erect position will not infrequently suffice to alter at once its character, so that it will become feeble, small, and 150 per minute. The experiments of Traube, which have already been mentioned, afford an explanation of this phenomenon so simple that it can scarcely be else than true. The action of the drug in such a case is verging upon the point at which the pulse-rate increases, and the arterial pressure falls, owing to the partial paralysis due to over-stimulation. Whilst the patient is recumbent, the line is not passed over, but the additional stimulation of the erect position carries the circulatory system beyond the limit of simple stimulation, and the over-effects of the drug are at once manifested.

Dr. Hanot recently reported to the *Société de Biologie* in Paris a case in which uræmia, supervening on general paralysis, was diagnosed by the symptom pointed out by Bourneville,—a rapid and general decline of temperature.

GONORRHŒA AND STRICTURE TREATED WITH URETHRAL SUPPOSITORIES.

BY HENRY E. WOODBURY, M.D.

In an age so progressive as that in which we live, it behooves the practitioner of medicine to keep up with the spirit of the times. Many theories that in years gone by were considered orthodox by our profession have long since fallen to the ground; and, no doubt, many that now obtain will meet with a similar fate in the future. This cannot fail to be the case so long as the science of medicine is not an exact science, and the type of diseases is so subject to change. While, therefore, old ideas are becoming obsolete, and new theories are springing up to take their places, it becomes doubly imperative upon the members of our profession that they investigate calmly and carefully every new plan presented for the treatment of diseases, as the community must look to us for relief from suffering. If we are unable to afford this in cases that are remediable, we shall incur that most unpleasant of all imputations,—inefficiency in the discharge of our professional duties.

Believing that any and every improvement upon old and established modes of treatment should be communicated to the profession, I propose to give a brief outline of my experience in the management of gonorrhœa and stricture,—diseases that often tax in the highest degree the skill, as well as the patience, of the physician or surgeon.

As in the treatment of fractures and some uterine diseases a certain amount of mechanical ingenuity is essential to success, so in regard to the diseases we are about to consider in this paper does the same fact obtain with equal force,—diseases as wide-spread as the race of man, brought on by his own imprudence (in the majority of cases), and often so long neglected that they assume an almost incurable type.

In 1867, the March and April numbers of the *Lancet* contained articles on the treatment of gonorrhœa by the eminent surgeons connected with the London hospitals. These I read with interest, and, reflecting upon the pathology of the disease, I determined to ascertain what the effect would be if I made my applications to the parts affected in such a manner as to have them longer retained in contact with those parts than they could possibly be by the old method of injection. I therefore prepared certain ointments of suitable consistency, to be applied with a female or common gum catheter. The medicinal agents used were nitrate of silver, calomel, sulphate of zinc, and bismuth. Of the first I seldom used more than three or four grains to the ounce of soft lard, sometimes rendered softer by the addition of a little glycerine. Of the others I used from five to fifteen grains to the ounce. A patient presented himself. I first examined the urethra with a catheter, in order to ascertain how far up the passage the disease extended. It proved to be an incipient case, and I proceeded as follows:

Forcing into the two openings near the end of a female catheter as much of one of the ointments above described as I could, I passed the instrument

well up the urethra, and, by means of a syringe-bulb attached to it, forced the ointment out into the passage, after which I slowly withdrew the catheter. The application was made after micturition, so that the remedy might be kept as long as possible in contact with the parts.

I directed the patient to take, during the day, flaxseed tea containing a little bicarbonate of potash, and an occasional saline cathartic, if required. In a comparatively short time I discharged my patient cured. I think about six or seven applications were made. In several other cases the plan worked well, but the trouble attending the application led me to try the method recommended by Mr. Henry Thompson (*London Lancet*, May 12, 1866). I endeavored to make suppositories, or soluble bougies, by combining nitrate of silver, tannin, etc., with cacao butter. In this I failed, as in every case the silver was precipitated in the form of an oxide before the cacao butter would harden. Being still sanguine, and determined to succeed if possible in testing this idea, I called on Mr. F. S. Gaither, a skilful pharmaceutist of this city, whom I found ready and willing to assist me. After several trials we succeeded in producing the first urethral suppositories ever used in this city, and I believe the first ever used in this country. Our failures in making the bougies at first came from melting the cacao butter. We found it far better to rub the nitrate well in a drop or two of glycerine, and then incorporate it with the shavings of cacao, upon a smooth white-pine surface, by means of a spatula.

The first case in which I used the urethral suppositories was an exceedingly obstinate one.

J. S. B., aged about 40 years, plethoric habit, bilious temperament, weight about one hundred and seventy-five pounds. Had led a reckless life; was much addicted to stimulants; had often suffered from gonorrhœa, which he said "stuck like a brother when it once commenced." It was complicated this time with chancre of simple type. When I suggested the suppositories, he at once said, "No, doctor; treat me the old way. I always have to take large doses of copaiba and cubebs, when I am elected."

The only effect produced by the remedies generally used in such cases was, at times, a slight diminution in the amount of discharge. At the end of six weeks he concluded to try the suppositories. From this time the disease began to yield to the treatment, and in two weeks I discharged him cured. I should, perhaps, add here that the only medicine taken by the mouth, after the resort to suppositories, was tincture of iron in tonic doses.

In many other cases of a milder type, the results of this mode of treatment proved no less satisfactory to my patient than to myself, and for years I have not been obliged to resort to nauseating drugs in treating this troublesome disease. I sometimes give the oil of erigeron or tincture of iron, and always direct my patient to take flaxseed tea with bicarbonate of potash. I have generally found that if taken in hand early the disease will yield to this treatment in from one week to ten days.

In a paper read before the medical society of this district in 1868, I predicted that urethral suppositories would be for sale at our drug-stores, like any other ordinary remedy; and that prediction has been verified.

Encouraged by the success that had attended my use of suppositories in gonorrhœa, I determined to try them in that troublesome complication, stricture. My *modus operandi* was as follows:

Examining the urethra with a steel sound of medium size, and finding a stricture, I endeavored to pass it. This operation was generally attended with a certain amount of syncope, and a slight flow of blood from the parts. In some cases, on account of great nervous excitability, I was compelled to postpone the operation for a few days. As soon, however, as I had succeeded in passing an instrument, I applied to the seat of the stricture the ointment, as described above, to be followed by the introduction of a suppository at night. Every third or fourth day a larger sound was passed, and the ointment and suppository used. The only internal remedy I ordered was flaxseed tea with potash; which, by neutralizing the acidity of the urine, renders it less irritating to the sensitive membrane in the act of micturition.

In a case of more than two years' duration, by this method a cure was effected in three weeks, the sound having been passed but six times. The patient, when he came to me, considered his case incurable. In 1868 or 1869 he married, and up to the time that he removed to the South (two years after) he experienced no further trouble.

I will refer to but one other case. A young man contracted gonorrhœa in 1865. He admitted that he had suffered from subsequent attacks during 1866 and 1867. He came to me in 1868. In his case I found stricture complicated with spermatorrhœa. He was thin, anæmic, and very much depressed in spirits. The stricture was treated as in the former case. Diluted phosphoric acid, with strychnia, was ordered for the complication. The patient was discharged cured in thirty-five days from commencement of treatment.

I have treated all of my stricture cases in this way since 1868. They have not been numerous (not exceeding in number fifteen or twenty), and I recall but one case in which I was unsuccessful. This was an old and a hard case, the symptoms being constantly aggravated by the intemperance and irregular habits of the patient.

My opinion of the utility of urethral suppositories is derived from actual experience in their use; and one instance that just comes to my mind is well worth a place in this paper. A lady consulted me relative to a urethral trouble, in 1869. She had used, without benefit, several remedies procured for her by a friend. Not wishing to subject her to an examination, I ordered for her six suppositories, and directed her to pass one into the urethra every night, keeping it in place by means of a compress and napkin. She was also directed to take the flaxseed tea. In a week she was completely cured. About three years after this, I received a note from the same lady, requesting me to send her by the bearer a recipe for the same kind of suppositories she had

used before, in which she said, "You need not take the trouble to call and see me, doctor, for I know the same treatment is all I require." When, some days after, I called to learn the result of the treatment, she informed me "it was all right."

I have used, in the form of urethral suppositories, the following remedial agents: tannin, persulphate of iron, nitrate of silver, and morphia. I consider those of nitrate of silver and morphia the most efficient. I have them made about the diameter of a No. X. or XII. catheter, and about two inches in length. One of these is passed well up the urethra, after voiding the urine, by the patient when he retires at night, and the organ is enveloped in old muslin, to prevent the linen from being soiled. I have no doubt but that the nitrate is, in a measure, decomposed during the process of blending it with the cacao butter; it may become pretty well oxidized. Be this as it may, results of treatment speak for themselves, and it is with these that we have to do in this paper.

The grounds upon which I advocate the use of suppositories in these diseases may be stated briefly as follows: By their use in gonorrhœa the remedy is kept longer in contact with the unduly-active mucous membrane than by any other method; while in stricture their lubricating qualities exercise a soothing effect upon the irritated surface, and prevent too rapid healing of the parts.

Will not some one who has the opportunity to treat these diseases frequently, give urethral suppositories a trial, and favor us with the results of his experiments in this direction?

WASHINGTON, D.C., April 3, 1873.

TRISMUS NASCENTIUM — A CASE SUCCESSFULLY TREATED WITH CHLORAL.

BY G. TROUP MAXWELL, M.D.,
New Castle, Delaware.

IN the whole catalogue of ills which flesh is heir to, there are few, if any, diseases which present so appalling a mortality record as trismus nascentium. The testimony of many extensive practitioners, who have seen a great deal of it, is that they have never known a case to recover. Its hitherto unchecked ravages in certain sections of the world invest it with a deep and solemn interest, and anything that will afford a reasonable hope of getting it under control would be hailed with delight. My own experience with the disease in the States of Georgia and Florida, in a large practice, running over more than twenty years, with the single exception which I am about to report, does not differ from that of the large majority of those who have written upon the subject. It was my ill fortune to encounter, especially in the earlier years of my professional life, quite a number of cases, with the same unvarying result; the sufferings of the little ones always ended in death. There was, therefore, no accident of the lying-in chamber which was more profoundly dreaded, and not one against the happening of which more precaution and care were exercised. It is true that most of the cases occurred among the negroes and the poorer classes of whites; but it is equally true that cases did happen in the families of the wealthy, cultivated, and refined. Thorough ventilation, absolute cleanliness, good nursing, and everything that thought could suggest and money procure, were sometimes unavailing to prevent the appearance of this terrible malady.

Having read with much care and interest the articles upon this disease from the pen of Dr. J. Marion Sims, which appeared in *The American Journal of the Medical Sciences* in 1846 and 1848, and having been deeply impressed by the then novel views of their author, upon entering the profession the latter year, I then, as indeed I have ever done since, made careful examination of the heads of the children, and diligently searched for the displacement of the cranial bones, to which, and the consequent pressure upon the medulla oblongata, that writer attributed the whole trouble. In some instances there was displacement, but in others there was none discoverable; and the application of the procedure recommended by Dr. Sims, even when it restored the bones to their proper places and relations, failed to arrest the disease: so that after repeated trials of the plan suggested by him, without reaching the anticipated gratifying results, and after finding cases of trismus in which there was not any discoverable displacement of the cranial bones, and not unfrequently displacement without trismus, I lost all hope of affording relief by the measures proposed.

My expectation of favorable results was aroused and temporarily sustained by the publication in the Charleston (S.C.) *Medical Journal and Review* of two cases successfully treated by Drs. Gaillard and De Saussure, of that city, with Cannabis Indica; but a faithful trial of the remedy, in the doses and according to the formula employed by these gentlemen, gave no encouragement. Indeed, I had exhausted the resources of our art, so far as I was acquainted with them, in the treatment of this malady, but without avail; and I resorted to every expedient known to prevent it. In this latter idea I have believed that I was more successful. For several years past I have invariably dressed the funis of every infant I delivered with balsam of copaiba. Whether the relation of cause and effect subsists between balsam of copaiba, so used, and the result of absolute exemption from trismus, in my practice, I am not prepared to assert; but the fact obtains that I have not had a single case of that disease to occur when I have assisted at the accouchement since I have been in the habit—now some twelve or fifteen years—of using this article as a dressing for the funis. Nor would I seem to claim the practice as originating with myself; although I cannot now remember to whom I am indebted for the suggestion. I have an indistinct recollection that the idea was obtained from one of the Southern journals, and that it was the practice of a resident of one of the West India islands. The cases of trismus which I have seen in the last twelve or fifteen years have all occurred in infants which were delivered by other physicians, or by nurses.

In October, 1870, whilst residing in Jacksonville, Fla., I was called to see a female infant seven days old, who was laboring under a well-marked attack of trismus. I had been engaged to attend the mother in her accouchement, but, for some reason, she was intrusted to the care of a nurse only. On inquiry, I learned that the labor had been natural in every respect, and until that morning mother and infant were seemingly doing well. The first suspicious indications which they had perceived were inability of the infant to seize the nipple as firmly and to draw the milk as well as she had done, and almost simultaneously a change in the tones of the child's voice. I would remark that this latter sign—a peculiar hoarseness and huskiness of the voice of the infant—is, according to my experience, among the earliest and surest indications of trismus, and is a valuable diagnostic symptom in the early stage of the disease, before its characteristics are fully developed. Satisfied, after a careful examination, of the nature of the attack the infant was laboring under, I gave, of course, a most unfavorable prognosis.

Chloral had not at that time been long in use. I had introduced it into Jacksonville the winter previous, and, besides the favorable accounts of its action, with which the journals in Europe and in this country teemed, I had been gratified by my own experience with it in cases of spasmodic affections. With little or no hope of deriving benefit from its use in this case, I determined, nevertheless, to employ it. Of the following,—

℞ Chloral. hydrat., gr. vj,
Syrup. simp.,
Aquæ, āā ʒj,

I directed one-fourth to be administered every two hours. The effect of the first two doses was to produce sound and seemingly natural sleep, during which the spasms were suspended. On awaking, the spasms recurred; but it was thought they were less violent. In the evening I directed the chloral to be given often enough, and only when required, to keep her asleep all night. The next morning the amelioration of her symptoms was quite perceptible; she nursed with greater ease; and when, after prolonged intervals, the spasms returned, they were manifestly less rigid. The effect of the chloral was maintained throughout that day and the next night, with steady progress of the case towards recovery, the intervals between the doses being increased in length as the disease diminished in severity; and after the third day all treatment was discontinued without a recurrence of the trismus.

From that time the infant grew rapidly; but during her fourth month a distinct development of hydrocephalus was observed. Was there any connection between the trismus and the effusion of water into the cavities of the brain? This inquiry suggested itself, but I am unable to respond satisfactorily. Not long after this I moved out of Florida, and lost sight of the case.

Since this case occurred I have seen reports of several cases of trismus nascentium successfully treated with chloral. They confirmed the hope that the result in the case just described was not an accident merely,—a simple coincidence, or *post hoc*,—but was, in fact, a *cure*, the result following the administration of chloral as legitimate and proper effect,—*propter hoc*. For that reason, and in that belief, I give it to the profession. Possibly this valuable addition to the physician's *armamentarium*—chloral—will invest this much-dreaded disease with less sombre colorings; at least it should receive a faithful trial.

Treatment of Basedow's Disease (*The Practitioner*, March, 1873).—The three essential features of Basedow's disease are palpitation and frequent action of the heart, swelling of the thyroid gland, and exophthalmos. Its relations to chlorosis are obvious, as its occurrence in females chiefly, and its frequent association with irregularities after menstrual function, show. Nevertheless it occurs in men, and even in children. Drs. Eulenberg and Guttmann, in speaking of the mode of treatment to be adopted, remark that whilst formerly tonics were very generally employed with the object of improving the blood, as well as remedies that lowered the action of the heart, notwithstanding that experience demonstrated how little benefit was to be obtained by these means, in recent times the cure of the disease has been attempted by applying continuous electrical currents to the sympathetic in the neck. Dusch, it appears, was the first who adopted this means in a case which had long been otherwise treated without effect, and found that the application of from ten to twenty elements reduced the pulse from 130 to 70, and even to 64, in the minute, the exophthalmos at the same time undergoing considerable diminution. MM. Guttmann and Eulenberg tried the same means in 1867, and found that in a woman suffering from the disease, and having a pulse-frequency of 108 to 130, with unusual tension of the carotid, upon galvanization of the cervical sympathetic with a very weak ascending current of only six or eight elements, a gradual fall of the pulse-frequency took place from 124 to 84, and even to 70, with coincident diminished tension in the carotid and radial arteries. This plan of treatment, however, was not continued long enough to cause much diminution in the size of the tumor of the thyroid or of the exophthalmos. Since then they have applied the current in four other cases, and in all with the effect of ameliorating the cardiac symptoms, but in none long enough to cause material improvement of the other symptoms. Chvostek has made numerous experiments on galvanization of the sympathetic in these cases, and in no less than thirteen of them has nearly effected a complete cure. In his hands the influence on the gland was well marked, whilst it was less distinct on the activity of the heart. Moritz Meyer also reports four cases where the thyroidal tumor was by the same means almost entirely abolished.

The Non-Identity of Varicella and Smallpox.—In an article published on the above subject in the *Allg. Wiener Med. Zeit.* (No. 7, 1873), Dr. Fleischmann states that varicella is a distinct disease from smallpox, and adduces various clinical and experimental proofs in support of this view. Among the clinical arguments are the following: Vaccination exerts no influence on the development of varicella; varicella attacks equally vaccinated and non-vaccinated subjects; recent varicella does not preserve from smallpox; varicella never gives smallpox, but true varicella through contagion. The experimental proofs may be summed up thus: Inoculation of varicella produces neither variola nor varioloid; inoculation of varicella generally presents a negative result in vaccinated and non-vaccinated subjects; in some exceptional cases true varicella has been produced; the local results in secondary inoculation of variola are negative; the pustules of varicella cannot be considered as conveying contagion in the same manner as the pustules of variola.

Curious Case of Criminal Abortion.—Dr. T. G. Thomas, in the *American Journal of the Medical Sciences* for April, 1873, records a case in which the wife of a physician used an umbrella-wire 17½ inches long to produce abortion, *wounding the right lung*, and inducing death by pneumonia on the sixteenth day.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 3, 1873.

EDITORIAL.

A LIFE-INSURANCE CASE.

THE law reports of this city recently contained an item of interest to life-insurance companies and their medical examiners. John H. Allen, the executor of a deceased person,—Edward Carroll,—sued the World Mutual Life-Insurance Company of Brooklyn for the amount of a policy on the life of the said Carroll, payment of which was refused on the ground that at the time of its issue the medical examiner had been deceived as to the physical condition of the applicant. Two other companies had refused to insure him, as in the opinion of their physicians he was suffering from incipient consumption.

The judge (McKennan) charged the jury that the point for them to decide was whether the contract was made in good faith on both sides: if Edward Carroll had deceived the company intentionally, the claim was vitiated, but if not, the verdict should be for its payment. The case went against the company; but the verdict was set aside, and a new trial ordered.

An instance like this strongly illustrates the responsibility of the medical examiners of life-insurance companies. We well know that some examiners, and some companies, are far more lax than others in their scrutiny of applicants. But the proper rule of taking none but sound lives, so that the risks assumed shall be those of the average only, should be rigidly adhered to, in justice to all parties concerned; and whenever this rule is slackened, the integrity and security of the company and its members are by so much impaired. It is true that for a few years the easy admission of applicants makes a larger income, and perhaps more flattering dividends, and that the lapsing of some policies may lessen the actual loss; the two together may for a time even cover it up; but it is also true that just these rotten policies are the very ones on which, for the short time they exist before becoming claims, the premiums are most regularly paid.

We believe, from actual experience in the matter for many years, that attempts at cheating life-insurance companies are far more frequent than would be generally supposed. Family physicians are too ready to give certificates of good health, or at least of assurability, to patients whose favor they are loath to lose. One gentleman, very prominent in the profession, was known by us to advise a lady of very delicate constitution "to apply for life-insurance just now, while she was, for her, so well."

Hence it behooves the companies to exercise great care in the selection of their medical examiners, and to look well into all cases of loss, so that if they are due to careless or incompetent scrutiny of the applicants, it may be known. And the examiners should never forget that they are the guardians of the interests of their employers, charged with the duty of rejecting all but suitable applicants. The whole business has grown to be so enormous, involving so many and such varied interests, and such a vast aggregate of capital, that it might well be far more frequently and freely discussed.

THE ASSOCIATION MEETING.

DURING the coming week, the usual yearly congress of doctors will take place at St. Louis. There is no reason to suppose that the session will be of either more or less consequence to the profession, or to the world at large, than those of former years. Our own city, so far as we know, will be but meagrely represented, the private business of most of our physicians being in every way more attractive and profitable than either the deliberations of the Association or even the generous hospitality of our Western brethren.

We have so fully and so repeatedly spoken of the defects of the system under which this annual congress is held, and of the palpable failure of its practical workings,—and we have so little hope of such a change as should make it a truly representative affair, having influence with the mass of the profession,—that we need not pretend to regard it, as

now constituted, with either profound respect or lively interest. Nor need we at present renew our specifications against it. We can only say, with St. Paul, "my brethren, these things ought not so to be."

The propositions contained in the letter of our respected friend, Dr. Gross, published in our issue of April 5, do not seem to us to meet the difficulty. It may possibly be that some action will be taken, either by the Association or by a few of its leading members, towards putting things on a better basis; if not, we shall try again to excite an interest in the subject during the interval between this and the next meeting.

We have made arrangements for reports from a special correspondent of whatever may transpire at St. Louis.

IN our issue of March 29 there was an account of a case in which ligation of the subclavian artery was performed at the Jefferson Medical College, by Dr. Maury. Our attention has been called to the fact that the reporter made the serious error, on page 406, of stating that the vessel was secured by means of a *silk* ligature. The material used was *fine silver wire.*

The importance of this correction will be at once evident, and we trust it will be known and noted by all who are interested in the subject. The statistics of the operation in question are so limited in extent that every case placed upon record should be accurate in the minutest detail.

CORRESPONDENCE.

LONDON LETTER.

[*From Our Own Correspondent.*]

The General Medical Council of Education and Registration—The Curriculum of Medical Study—The System of National Conjoined Examinations—Visitation of Examinations—The Contagious Diseases Acts—Medical Officers of Health—Registration of Midwives—Professor Tyndall.

LONDON, April 9, 1873.

DURING the last week the General Medical Council of Education and Registration have been holding their annual session in London. This is always rather an interesting medical event. The Council includes official delegates from every university and medical corporation chartered by the state to confer medical licenses and degrees throughout Great Britain. Their assembly is always the signal of profuse hospitalities; and they discuss matters of considerable importance. Thanks to their labors, no medical student can now be registered until he has passed a preliminary examination in Latin, French, English composition, arithmetic, algebra, and Euclid; nor can any such student subsequently be admitted to examination for a degree until he has passed through a prescribed curriculum of education lasting for four years,—three of which must be spent in a medical school attached to a hospital with not less than one hundred and fifty beds, and a museum and other appliances of instruction on a corresponding scale, which has been "recognized" as suitable by the examining bodies. The fourth year must be spent in acquiring professional knowledge either at one of these hospitals or at some other hospital, school, or place affording adequate means of instruction. Notwithstanding these restrictions, however, it is feared that, under the influence of competition for fees, some of the examining bodies (in Scotland and Ireland especially) do not impose a sufficiently severe test upon the candidates for their diplomas. The efforts of the Council lately, therefore, have been devoted chiefly to the attempt to procure united action by inducing all the examining bodies in each of the three kingdoms to unite in forming conjoint examining boards in each kingdom, for the purpose of establishing a uniform minimum standard of examination. This effort has not been altogether successful, partly owing to legal difficulties attending such united action, and partly to reluctance of the Scottish bodies to fall in with an arrangement which would rob them of their individual right of action and lessen their profits. Their principle is "small profits and quick returns." Legislative action will be attempted, but, from what I know privately of the opinions of leading members of the government, it will not succeed in the shape proposed. Lord Ripon has a strong opinion that a more complete measure is necessary than any which the Medical Council are likely to propose; and his colleagues in the Cabinet will be guided by him in the matter. Meantime, exercising powers conferred by clause 19 of the Medical Act, the Council will resume strict visitation and inspection of the respective examinations by paid visitors; and this will exercise a most salutary effect. On the whole, the tests for diplomas have risen to a very high standard lately,—so high that there is some fear that a sufficient supply of practitioners ready to do the hard every-day work of the profession in poor districts will presently with difficulty be obtained. Already there has been a general rise in the fees of practitioners; and one of the senior surgeons of St. Bartholomew's told me, a few days since, that he finds great difficulty in getting young men to accept colonial and county appointments such as a few years since would have been eagerly sought after by a host of applicants.

Among the least inviting branches of every-day practice is "cheap midwifery," and this is falling gradually more and more into the hands of midwives. It is calculated that there are ten thousand midwives practising in Great Britain; and that from thirty to sixty per cent. of the women in many rural places and manufacturing towns are delivered by midwives. There is, however, but a very scanty machinery for educating them, and no authorized examinations for them, nor any register of

qualified persons. The result of the prevalent ignorance of this class of women is a great excess of mortality among lying-in women, and an unrecorded but pitiable mass of additional suffering inflicted on our poorer sisters in their hour of greatest need. The necessity is accordingly felt by many of the members of our profession for taking means to provide opportunities on a large scale for training midwives, and establishing an examining board and a public register of trained midwives. A deputation of the Parliamentary Committee of the British Medical Association has waited upon the president of the Local Government Board on this subject. Mr. Ernest Hart, as president of the committee, made a lengthened statement to that minister on the subject. Mr. Stansfeld returned a warmly favorable answer: he had frequent occasion, in connection with the administration of poor-law medical relief, to lament the deficiencies which the deputation pointed out; and he expressed a desire to do all in his power to promote state assistance to the scheme proposed. He undertook to bring the matter before his colleagues in the Cabinet. Dr. Acland, F.R.S., is moving in the same direction in the Medical Council, and Dr. Aveling in the Obstetrical Society; so that there is a fair prospect of something being done shortly to secure state examinations for midwives in this country.

The agitation against the Contagious Diseases Acts continues to be carried on fiercely in the provinces by the ladies chiefly, aided, however, by a certain section of churchmen, and by a number of gentlemen who describe themselves as belonging to the school of Mr. Mill. The whole medical profession, with the exception of a very few, are strongly in favor of the acts, on the ground of the physical benefits, and because it has been shown that by bringing under supervision the class of prostitutes who haunt garrison towns (to which alone these acts apply) they have tended to improve the morality of these towns, have led to a great reduction in the number of public women, to the reclamation of a considerable number of them, and to the introduction of decency and outward propriety where the opposite conditions previously prevailed. All this has been generally conceded: nevertheless, "the antecedent moral objections" to measures which virtually aim at providing healthy prostitutes for soldiers and sailors, and so offer immunity to immorality, are so strong in the minds of many excellent and thoughtful persons that the future stability of the acts may be regarded as doubtful. No measure for repealing them will be passed by this Parliament; but it will be a hustings question at the ensuing general election; and it may possibly pass in the next Parliament.

Under the recently passed Public Health Act, medical officers of health with highly important sanitary functions are being appointed in every district of England. Some are very highly-paid officers,—receiving from £600 to £800 sterling a year; others, acting in smaller localities, receive much smaller salaries; but altogether they are very handsome appointments, and, as many hundreds have been made, and some hundreds are still to be made, they will give a handsome addition to the income of the profession. This is only just; for a large amount of work preventive of disease has hitherto been done by the profession without payment; and by preventing disease and arresting epidemics they will save large losses to the country, and diminish professional receipts from attendance on sickness.

The Societies have been very active during the last few weeks. The Pathological Society of London, especially, has been the scene of a protracted and very able debate on the anatomical relations of tubercle. It is, however, still unfinished. I will give some account of it in my next letter, by which date it will probably have been concluded.

Professor Tyndall has been warmly received on his return to London. He gave, last Friday, a lecture on Niagara, full of characteristic keenness of observation, skilful generalization, and happy turns of thought. It was warmly applauded by a crowded audience.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

Semi-Monthly Meeting, April 9, 1873.

Reported by James S. Bailey, M.D.

Dr. Albert Van Derveer, President, in the chair.

LIGATION OF THE SUBCLAVIAN ARTERY FOR AXILLARY ANEURISM.

DR. JAMES H. ARMSBY addressed the Society on this subject, as follows:

My first operation was at Glens Falls, November, 1863, for axillary aneurism. The patient was John Ferguson, merchant, æt. 28. He had lost his right arm by the accidental discharge of a cannon in July previous. The stump was healed, and was apparently sound, until the following September, when a pulsating and painful tumor was formed in the axilla. This increased rapidly in size, until the day before I was called, when the sac was ruptured by an effort to put on his coat. He lost in a few moments two or three quarts of blood. He fainted, and was almost pulseless several hours, during which time the opening was closed by a compress, fastened by adhesive straps crossed over the shoulders.

When I arrived I found him in bed; pulse 130; skin cool and pale. The aneurismal tumor had filled, and was pulsating strongly under the dressings. I decided to operate immediately.

The first incision extended along the clavicle from the mastoid to the trapezius muscle, and was about three and a half inches in length; the second, vertical, intersecting the first near the middle. In dissecting up the flap, it became necessary to ligate three small arteries and the external jugular vein. The vein was secured by two ligatures, and divided between them. The clavicular portion of the mastoid was divided, and the deep cervical fascia.

The clavicle was carried upward to such an extent by the great size of the tumor as to render it extremely difficult to reach the artery. While detaching the fascia and large veins which cover the artery at the border of the scalenus muscle, I was startled by a slight gurgling sound, and the presence of air-bubbles at the deep-

est part of the wound, and immediately covered the spot with my finger. There was a tremor and slight convulsive movement, during which the pulse and heart were greatly disturbed, indicating the introduction of a small quantity of air into the circulation. After a moment of extreme anxiety, the operation was resumed, putting the ligature around the artery just under the outer border of the scalenus muscle. The deep cervical and supra-scapular arteries were both exposed, and held to one side. They came off on the cardiac side of the scalenus, and, as the loss of blood had been so great, I did not deem it safe or necessary to ligate them.

The greatest difficulty of the operation consisted in separating the great veins which completely encircled and obscured the artery. I passed the ligature from below upwards, securing a good view of the point of ligation, and applying the test of pressure before tying the knot. As soon as the ligature was drawn tight, the pulsation in the tumor ceased. An anodyne was administered, and the patient had a good night's rest. Under the use of a generous diet and tonic course of treatment, he improved rapidly, until the tenth day, when the skin over the tumor became discolored and painful. I was again called, and laid open the sac freely, removing nearly a quart of coagula and sanguino-purulent fluid. After this his recovery was rapid and complete. The ligature came away on the twenty-ninth day.

Case II.—In October following, I operated a second time for the relief of secondary hemorrhage which threatened immediate fatal results. Major Jacob C. Clock, U.S.A., was wounded by a minié ball at the battle of Occoquan, Va. The ball entered in front of the shoulder-joint, and passed through the axilla, fracturing in its course the scapula quite extensively, coming out near the spine. The axillary artery, or some of its larger branches,—probably the sub-scapular or internal circumflex,—were wounded. He suffered much from loss of blood, shock to the system, and exposure on the field previous to his removal to the military hospital at Winchester, Va. While in the hospital he lost much blood from repeated hemorrhages, and had chills and fever continuously.

He reached his home twelve days after the wound was received. During the next ten days he seemed to improve in strength and health. On the twenty-third day after the wound he had a sudden and profuse hemorrhage, losing a large quantity of blood. I was called by telegraph. When I arrived, he was ex-sanguine and pale; pulse 130; and the wound swollen and unhealthy. As the only surgical means available, I decided to ligate the subclavian artery.

The operation was done by candle-light, in the presence of several medical gentlemen. The incisions were made, as in the other operation, over the clavicle and along the posterior border of the mastoid. The external jugular vein and three superficial arteries were ligated. During the first incision, in dividing the deep cervical fascia, two larger branches had to be tied. A large nerve, a branch of the axillary plexus, was situated over and rested on the artery, and was uplifted by every pulsation. On casting a ligature under it, and holding it to one side, the artery was found directly under, and ligated between, the scaleni muscles. The anterior scalenus had to be divided, near the point where it is crossed by the phrenic nerve, which was carefully preserved.

The pulsation and hemorrhage ceased immediately, and the patient lost but little blood during the operation. Everything promised a favorable result during the first twenty-four hours. He rested well, took sufficient nourishment, and there was a manifest improvement in the pulse and general condition. Forty-eight hours later he had a severe chill, and on my second visit I found the gunshot wound in a gangrenous state, and the patient rapidly sinking.

He died on the twenty-sixth day after the wound was received. The operation was successful as regards the suppression of the hemorrhage, and prevented an immediate fatal result.

The condition of the patient, and the exposure on the field and while travelling, had a controlling influence in the final termination of the case.

Case III.—Wm. Nash, a guide in the North woods, was rowing a boat on Cedar River, June, 1872. His boat fell into the current, and was in danger of going over the falls. While using extraordinary effort to avoid the danger, he felt a sharp pain in the axilla, and a sensation as if something had been torn or lacerated. A swelling soon followed, attended with throbbing pain and inability to move the limb. The tumor increased quite rapidly, carrying the shoulder upward, protruding forwards under the pectoral muscle. On the 8th of March he was taken to Warrensburg, and placed under the care of Dr. McNutt, who immediately telegraphed to me, and started at once for Albany with the patient.

When he arrived he was greatly reduced by the suffering and fatigue of the journey. For several weeks the pain had been severe, preventing sleep, and exhausting his strength. The pulsation was strongly expansive over the greater part of the tumor.

On the 10th of March the operation was performed in the amphitheatre of the hospital, in the presence of the medical and surgical staff, and other members of the profession.

An incision was made along the course of the clavicle three and a half inches in length. The superficial and deep cervical fascia and clavicular portion of the mastoid muscle were divided; but one superficial artery required the ligature. The external jugular was compressed, and not divided. The artery was reached under the anterior scalenus muscle, which was detached from the rib three-fourths of an inch to uncover the artery. The deep transverse cervical artery was given off from the subclavian close to the border of the scalenus, which rendered the division of that muscle necessary to reach the artery. The subclavian was ligated first. The ligature was passed from within outwards, pressure was applied with the finger, and the tumor ceased to pulsate; the knot was then secured. The transverse cervical was then tied half an inch from its origin; only three ligatures therefore were applied, and the patient lost hardly a spoonful of blood.

The wound healed kindly. The ligature came away on the fourteenth day. The tumor was gradually diminished, and the sensation and power of motion in the limb have been gradually restored. The cure has progressed until this time. He is walking about in the hospital, and a complete recovery is anticipated.

At the annual meeting of the American Medical Association, held in New York, May, 1866, a committee was appointed to report on the subject of ligation of the subclavian artery. I was a member of that committee. The report was made under the direction of Dr. Willard Parker, and the statistics collected by Dr. Wynkoop, a student of Dr. Parker.

At that time, 196 cases of ligation of the subclavian had been reported; 107 died, and 88 recovered; the result in one case was not given. The mean time for separation of the ligature was 21 days; the shortest time, 8 days; the longest, 113 days.

The subclavian has been tied in its first division 13 times, without one recovery. In its second division, 9 times, with 4 recoveries. In its third division it has been tied 174 times, with 83 recoveries. Out of 67 cases 29 have died of hemorrhage.

Dr. Rork [Koch ?] reports 185 cases of ligation of the

subclavian external to the scaleni muscles, of which 100 died, 82 recovered. The result in 3 cases is not stated. During our late war the subclavian was tied 17 times for hemorrhage, with but two recoveries.

Dr. HENRY MARCH remarked that it was remarkable that his father (the late Dr. Alden March) never had had occasion to ligate the subclavian artery in his long experience as a surgeon; but by reference to his case-book he found he had ligated arteries forty-three times, among which the profunda, external iliac, and common carotid were included.

SECONDARY SYPHILIS.

Dr. LEVI MOORE then addressed the Society upon secondary syphilis. He remarked that some years since he had read a paper on the subject of syphilis before the Society, when his remarks were confined more especially to the primary form of the disease, its character, distinctive features, and effects upon the human body.

He had been deeply impressed with the importance of this subject, both as it relates to the victim, whose vices self-impose this disease, and to that larger class to whom this disease is transmitted hereditarily or otherwise. It is a lamentable fact that by far the greater number of those who suffer either directly or indirectly from syphilis are in no way the authors of their sufferings. We are all so frequently brought in contact with this disease in its primary form, and at that period, too, when it is impossible to prevent the constitutional taint, that we need not wonder if it bears bitter fruit, involving in a common calamity the innocent as well as the guilty.

Dr. MOORE related the following case:

Several years ago Mr. N. placed himself under his care, who was at the time, and had been for a considerable period, suffering from a chancre on the glans penis. The case was complicated by phymosis. Cleanliness, the use of washes, the internal administration of mercurials in the form of pil. hydrarg., and afterwards protiod. mercury, with iodide of potass., finally effected an apparent cure. The remedies were continued for a long time, with the hope that but little if any of the virus of the disease remained in the system of the patient at its discontinuance.

Afterwards he married. His wife conceived, and miscarried at the expiration of three months. About the same time a troublesome ulcer, syphilitic in appearance and of large size, appeared upon his leg, which only disappeared after long and persistent use of the remedies mentioned. A second pregnancy occurred, and at the end of the seventh month his wife was delivered of a living child covered with syphilitic eruption and presenting most unmistakable evidences of constitutional taint. The child lived about one month, and then died. The mother, to all appearances, retains good health; and yet we cannot doubt but that sooner or later she will suffer from the effects of syphilis, introduced through her circulation from that of her unborn child.

Another case.—A young man, whom Dr. MOORE attended for secondary syphilis, and who had the characteristic ulcers about the mouth and fauces, was at the time attentive to a young lady of good family and character. Somewhat more than one year afterwards, Dr. M. was asked to prescribe for an eruption on the body of the lady, and was surprised to find it syphilitic; also to find a syphilitic sore-throat. He then learned that one year before she had suffered from a troublesome ulcer on her lip, which was long in healing.

Dr. MOORE continued, that he had introduced these cases only because they are pertinent to some further observations he had to offer on this subject. They are by no means exceptional, and probably many members present could recall similar cases.

Miscarriages frequently result from the effects of this disease, and, when the offspring is born alive, both mother and child are involved in one common misfortune.

The question was then asked if remedies could eradicate this disease from the system.

He said there were grave doubts, in the minds of careful observers, whether this disease, when once it has obtained a foothold in the human body, can ever be entirely removed. It is believed it may reappear or bear its legitimate fruits in syphilitic or scrofulous offspring.

The recognized difficulties in the way of curing those affected with this disease led to the trial of the principle of inoculation in a Swedish hospital. Patients affected with syphilis were repeatedly vaccinated with syphilitic virus, till a constitutional tolerance had been established and the virus ceased to produce any effect. Many cases were subjected to the treatment, and satisfactory results claimed. Although several years have elapsed since he read the statement, he had not learned that any other hospital had seen fit to continue the experiment.

He next directed the attention of the Society to a sanitarian view of this disease, and remarked that multitudes of our young men enter upon married life with their physical vigor tainted by this poison; wives and children alike suffer. Others still, unfaithful to their matrimonial relations, contract this loathsome disease and communicate it to their wives, and doubly entail it upon their children.

The importance of this subject has led to legislation on the matter of prostitution, and the city of St. Louis, and some others, have instituted a sanitary police to regulate prostitution, and in this way to protect the innocent from its evils.

The moral, as well as the sanitary, aspect of this proposition has been not a little discussed; and while it has been warmly commended on some hands, it has been bitterly denounced on others. It rests with the medical profession to shape and direct public opinion to the proper view of this question.

Dr. MOORE said that he had accomplished his object if, by remarking on this subject, he had awakened in the minds of the members of the Society a deeper interest in this important subject, and a more earnest desire to shield the innocent and unsuspecting from its destructive influences.

A general discussion arose from the reading of Dr. MOORE'S paper, in which nearly every member took an active part, each one giving his particular views upon the subject.

AMPUTATED CERVIX UTERI.

Dr. VAN DERVEER presented two specimens of amputation of the cervix uteri. One had been removed some time ago. The patient became pregnant in three months after the operation, but miscarried in consequence of over-exercise. To-day he had delivered her, at full term, of a healthy fœtus. The remarkable features were that no rigidity existed, and that the cervix appeared quite normal.

The second case was that of an unmarried woman, æt. 35, upon whom he had operated recently. There had been a difficulty in urinating for ten years past, the cervix having to be crowded up each time before the water was voided. There was found to be a longitudinal hypertrophy of the cervix, causing the organ to protrude when the patient was in the erect position.

Preparatory to the operation the patient was etherized, and the parts were exposed by a Sim's speculum, and the neck brought down by a silver wire passed around it. The amputation was then performed with curved scissors, 1½ inches anteriorly and 2 inches posteriorly. Four sutures were introduced to unite the edges of the mucous membranes.

She now menstruates normally, and already feels much improved. He preferred the scissors to the galvano-cautery, as the latter leaves a cicatrix, which can never be covered with epithelium, while by using the scissors the mucous membranes can be united by sutures and so be made continuous.

There is but little hemorrhage, as the silver wire acts as a tourniquet, and also aids in the operation by bringing the organ down.

REVIEWS AND BOOK NOTICES.

THE DISEASES OF THE STOMACH. Being the third edition of the "Diagnosis and Treatment of the Varieties of Dyspepsia." Revised and enlarged. By WILSON FOX, M.D., F.R.C.P., F.R.S., etc. 8vo, pp. 236. London and New York, Macmillan & Co., 1872.

The present edition of this work, besides being revised, differs from the two previous ones in containing a chapter on ulcer, and one on cancer of the stomach, as well as short articles on hypertrophy of the walls of the stomach, obstruction of the cardiac orifice, hemorrhage, dilatation, and softening of this organ. These additions render an already valuable work complete, and, as the author has spared no labor in its preparation, it is one of the most excellent treatises on the subject.

The best and latest authorities are freely quoted throughout the book, and we have the results of a considerable amount of original research and observation.

The first part is a general consideration of the symptomatology of the diseases of the stomach. Dr. Fox believes that in the inflammatory and irritative affections of this organ the appearance of the tongue undergoes changes indicative of the condition of the gastric mucous membrane, but that in the other disorders of the stomach the tongue is usually unaltered.

We are told that flatulence is generally the result of fermentative changes, and that gas is never, as has been supposed, secreted by the mucous membrane of the digestive tract. In the sudden flatulent distention of hysterical cases it is believed that most of the air is swallowed.

Acidity is thought to arise, in the great majority of cases, from fermentative action, but in some instances it is the result of a hyper-secretion from the mucous membrane.

Part second treats of the special diseases of the stomach, beginning with "atonic dyspepsia."

Under the head of gastritis the author considers acute and chronic gastric catarrh,—differing in this respect from those who consider gastritis a rare affection, due only to direct irritation from corrosive poisons, alcohol, etc., and occurring as a complication of other diseases. In addition to the acrid poisons, Dr. Fox gives as causes of acute gastritis, improper food, such as decomposing meat or vegetables, the drinking largely of cold water when the body is heated, and changes of temperature. He says there seems to be evidence that epidemic influences have something to do with the production of this disorder. Under the same head a very accurate description is given of sick headache, and, although the author regards the headache as usually a symptom of gastric catarrh, he seems disposed to agree with Dr. Anstie in looking upon the pain as a neuralgic affection. There is still, however, a great deal of discussion as to the true nature of *migraine*, as recent papers in *The Practitioner*, *Lancet*, and *British Medical Journal* will show.

Chronic catarrh includes a large number of cases of chronic dyspepsia, and the writer believes it to embrace the disorders described as "irritative," and even "nervous" dyspepsia. In the description of this form of the disorder the reader will recognize cases that he daily meets with.

The writer alludes to the opinion of some authors, that indigestion is often the immediate cause of phthisis. His own belief is that, when dyspepsia has preceded pulmonary disease, the same unhealthy constitutional condition has produced both affections.

The articles on ulcer and cancer are full of interest and information, while the references to authorities are even more numerous in this than in other parts of the book, and add greatly to its worth.

The paper and typography are good, and there are two fine engravings illustrating the microscopic appearances of the glands of the stomach in catarrhal conditions.

GLEANINGS FROM OUR EXCHANGES.

REMOVAL OF A NEEDLE FROM THE HEART—RECOVERY OF THE PATIENT (*British Medical Journal*, March 1).—Mr. G. W. Callender related to the Royal Medical and Chirurgical Society, at a recent meeting, the history of a man who for nine days followed his ordinary occupation in pain and with discomfort, having a needle fixed in the tissues at the apex of the heart. On the ninth day, in consequence of his statement and in view of the pain which he was suffering, an incision was made over the fifth intercostal space, and the broken eye of the needle was found on a level with the intercostal muscle. This extremity was seized, and the foreign body was withdrawn. The patient recovered without an unfavorable symptom. With this history, the exact position of the needle in the wall of the chest was given, as also was that of its probable position in the heart; the movements of the foreign body, caused by those of the heart, were figured, and their measurements were added. Some remarks were made upon recovery and duration of life after somewhat similar injuries, and an appendix of cases was given in the form of a table.

A discussion having arisen as to the actual penetration of the heart-substance by the needle, Dr. C. J. B. Williams said that the needle must have been buried to some depth in the substance of the heart. In animals on which experiments had been tried with pins, to ascertain the causes of the sounds of the heart, the introduction of needles caused at first violent action; afterwards the action was quieter. The needles always moved, and produced a friction-sound. Most likely there was adhesion here. It might be possible to introduce a needle, and so give an electric shock directly to the heart in suspended animation. Mr. Croft did not think the needle had penetrated the heart-substance. There were various reasons why he thought its end must have been free in the pericardium. A boy was brought to St. Thomas's with a needle supposed to be broken off in the substance of the heart. He died of pericarditis. The point was found projecting into the pericardium. It had caused laceration of the heart's substance, and pericarditis. Mr. Hulke said there was no difficulty about Mr. Callender's theory. There was much greater difficulty in accepting Mr. Croft's notion. The needle was really free at its outer end; and, attached at its inner end to the substance of the heart, it swung with its motions. Mr. Fairlie Clarke said in Mr. Croft's theory inconvenience was more likely to arise than in Mr. Callender's. Much more severe injuries had been recovered from. Mr. Callender said that if he had not

been quite sure as to the nature of the case, it would not have been worth while to bring it before the Society. The movements were exactly such as would be produced by the motion of the heart. It was marvellous how the man could go about his work for nine days in this state. The pain complained of a month after was doubtless due to nervousness. In the case of a child who ran a needle into a joint, he did not find the magnetic needle of much practical use.

The Cerebral Mechanism of Speech and Thought.—Dr. W. H. Broadbent, in a paper in the "Medico-Chirurgical Transactions," vol. lv., presents the following conclusions:

1. Words, as remembered sounds, will be represented by cell-groups at the summit of the receptive side of the nervous system, which, for reasons given, is supposed to be situated in the marginal convolutions of the cerebral hemisphere.

2. From these cell-groups, when definitely formed, impressions will be transmitted to a cell-area in the superadded convolutions, to which also impressions conveying to the mind the various properties of objects indicated by the words will be transmitted; all these impressions are associated, and the word is employed as the symbol for the resulting idea of the object.

3. Almost simultaneously motor cells in the corpus striatum are grouped for the production of articulate words under the guidance of the remembered sound in response to efforts at imitation, which are at first more or less parrot-like. The cell-groups for spoken words once formed are, however, employed almost exclusively in intellectual expression.

4. The receptive cell-groups for remembered sounds will be found in the marginal convolutions of the two hemispheres, which are symmetrically associated by the corpus callosum, and the cell-groups for spoken sounds will be found in the two corpora striata; but the absence of commissural connections between the superadded convolutions of the two hemispheres permits of the predominant, if not exclusive, education of the left hemisphere for the verbal expression of the product of intellectual action, as has been revealed by pathology. This is an efferent process, and does not imply the exclusive use of the hemisphere in thought.

5. The outlet for intellectual expression in spoken words, which are motor acts, is necessarily in some part of the marginal convolutions in relation by fibres with the corpus striatum, and pathology has shown this point to be the left third frontal gyrus.

6. The left third frontal gyrus being the outlet for expression, the left corpus striatum necessarily takes the lead in the production of spoken words, but a way round exists probably from the left to the right third frontal gyrus by the corpus callosum, and thence to the right corpus striatum. Thus speech, though temporarily embarrassed by damage to the left corpus striatum, is recovered; whereas, if the cortex of the left third frontal convolution is damaged, or its fibres, both to the corpus striatum and the corpus callosum, cut through, speech, having no other outlet, is lost.

On a New Mode of Treatment of Functional Dyspepsia, Anæmia, and Chlorosis (*The Practitioner*, March, 1873).—M. Brown-Séquard, in his "Archives of Scientific and Practical Medicine," in a paper on this subject states that in 1851 he had to treat a bad case of dyspepsia, and succeeded in curing the patient by a plan of treatment which deserves attention, though it was long ago adopted by Dr. Watson in this country in cases of obstinate vomiting. M. Brown-Séquard has employed this plan with complete or partial success in a number of cases of dyspepsia, of chlorosis, of anæmia, and also as a means of ameliorating or curing nervous affections caused by gastric disturbances or poverty of blood. In a number of instances where failure occurred it was found that the patients had not carefully followed the rules, and that the failure was, at least in a great measure, due to this lack of care. In two cases only some increase of flatulency and acid eructations took place during three or four days, when the plan was given up. In a case of dropsy, attended with anæmia, dyspeptic pains were increased for a week, when the plan was abandoned. The treatment consists in giving but very little of solid or fluid food, or any kind of drink, at a time, and to give these things at regular intervals of from ten to twenty or thirty minutes. All sorts of food may be taken in that way; but during the short period when such a trial is made, it is obvious that the fancies of patients are to be laid aside, and that nourishing food, such as roasted or broiled meat, and especially beef and mutton, eggs, well-baked bread, milk, with butter and cheese, and a very moderate quantity of vegetables and fruit, ought to constitute the dietary of the patients under treatment. This plan should be pursued two or three weeks, after which the patient should gradually return to the ordinary system of eating three times a day. M. Brown-Séquard's experience with the patients on whom he has tried the plan of feeding above mentioned, shows that the amount of solid food required by an adult is nearly always as follows: from twelve to eighteen ounces of cooked meat, and from eighteen to twenty-four ounces of bread. As regards the quantity of fluids he has always allowed, it has been notably less than the amount indicated by Dr. Dalton (three pints), and by Dr. E. Smith (four and one-half to five pints).

A case of spontaneous version is related by Dr. Stanley Haynes, in the "Transactions of the Edinburgh Obstetrical Society." Mrs. M., aged 37, in her eighth pregnancy, had a left occipito-anterior position of the head; the os was dilated to two inches. The patient, whilst seated upon the night-stool, felt a sudden and great movement within, followed by a sensation of the descent of the fœtus. She hastened back to bed; the breech and right foot were now found presenting, the dorsum of the child being towards the left foramen ovale, and in three pains the birth was completed.

MISCELLANY.

Medicine at Leipsic.—A correspondent of the *Lancet* quotes as follows from M. Léon Gautier: "In the Universities lie Germany's strength and the secret of her success." In 1870 Leipsic alone sent out to the war 400 of her 1668 students, of whom 55 never returned. Before their departure the Professors addressed them in the Town Hall, one saying, "If the French ask you where you come from, say, 'From Leipsic.' They will remember the name." The Medical Faculty, formerly third in importance after Jurisprudence and Theology, is now rapidly coming to the front,—the present session numbering nearly four hundred medical students, besides one hundred and twenty-one studying pharmacy. The senior of the Faculty, as he is of the whole University, is Dr. Ernst Heinrich Weber, Professor of Anatomy, who has held his chair for fifty-two years. There are also Dr. Radius, Professor of Hygiene; Dr. Wunderlich, ex-Rector and Clinical Professor; Dr. Crede, Professor of Midwifery; and Dr.

Wagner, Professor of Pathology and Pathological Anatomy; while physiology is represented by Dr. Ludwig; surgery by Dr. Thiersch; ophthalmology by Dr. Coccius; anatomy by Dr. His; and topographical anatomy by Dr. Braune. Our readers have, doubtless, recognized many of these names as of European reputation,—to say nothing of Dr. Czermak, a man of large private fortune, who lectures on physiology, and has provided in his own residence a commodious lecture-room and laboratory, with teaching-apparatus of every kind; the whole (lectures and practical arrangements) being free and open to all. There are also fourteen extraordinary Professors and twelve privat-Docents in the Medical Faculty of Leipsic, which, moreover, enjoys clinical resources of the best kind. In the suburbs there is the new large Infirmary, built on the latest and most approved principles; and in connection with it is the Clinical Institute, of which Professor Wunderlich is Director and first teacher, and Professor Thiersch Director of Surgical Clinics. The Infirmary is a one-story building, spread out in pavilions over an extensive area. In addition to it are the Pathologico-Anatomical Institute, under Professor Wagner; the Physiological Institute, under Professor Ludwig; and the Pathologico-Chemical Laboratory, under the Clinical Director, Professor Hofmann. A large new Anatomical Institute, towards which the Saxon Chamber a year ago granted 167,000 thalers, is in course of construction; and in another part of the town there is a Hospital for Midwifery and Women's Diseases, under Professor Crede. Professors His and Braune are Directors of an Anatomical Institute in conjunction with the old University buildings; while Professor Radius superintends a Pharmaceutical Museum, Professor Wagner a Medical Polyclinical Institute, Professor Schmidt a Surgical Polyclinical Institute, and Professor Thomas a District Polyclinical Institute. In an opposite part of the town there is an Institution for Eye Diseases, under Professor Coccius. Leipsic, the medical student will observe, is well worth a visit; while residence there is much cheaper, and, in a sanitary point of view, safer, than at Vienna or Berlin.

At a very full meeting of the Medical Society of the city of Wheeling and county of Ohio, held on Monday evening, April 14, the following action was taken with reference to their deceased fellow, Dr. Robert H. Cummins:

The melancholy announcement having been made to this Society of the death of Dr. Robert H. Cummins, an honored member and a former President of the Society, therefore,

Resolved, That in the death of Dr. Cummins this Society, and the community in which we live, have suffered a loss which will make this sad event to be long remembered and regretted.

Resolved, That the assiduity, devotion, and unusual skill and ability with which the deceased discharged his professional duties, joined to the courteous bearing which distinguished his conduct towards his medical brethren, and his uniform kindness of manner in his intercourse with his patients, gave him a symmetry and completeness of professional character which commands our highest respect, and is received by us as an example eminently worthy of our imitation.

Resolved, That the personal and social character of the deceased possessed traits not less deserving of commemoration than were his professional virtues, and we bear our testimony to his integrity of principle, his uprightness of conduct, and to his kind and sympathizing nature, which at once gave him the entire confidence of those to whom he ministered, and endeared him to a very large circle of ardently attached friends, in whose hearts his memory will long be kept green and unfading.

Resolved, That the members of this Society will in a body attend the funeral of deceased to-morrow at two o'clock P.M., and will wear the usual badge of mourning for thirty days.

Resolved, That the President of the Society be requested to present a copy of these resolutions to the family of the deceased, with the assurance of our sincere sympathy with them in this sad bereavement.

Resolved, That the foregoing resolutions be spread upon the minutes of the Society; be furnished for publication to the daily papers of the city, and to the medical journals.

Resolved, That Drs. Todd, Bates, Frissell, Ford, Hupp, Baird, Allen, and Hildreth, be appointed to act as pall-bearers.

R. W. Hazlett, *President.*
S. L. Jepson, *Secretary.*

A correspondent of the *Lancet* relieves his mind as follows:

"Killing two Birds with one Stone.—The stone in this case—not the first case of the kind—is a sermon. The preacher is Dr. Lambart, of Liverpool, who lectures on Sunday afternoons on the Body and its Diseases. Dr. Lambart is not only minister of Holy Trinity Church, but M.D. Dublin, and M.R.C.S. Eng. The lecture, as reported in a Liverpool paper, contains lively allusions to the case of Napoleon III., with complimentary references, in passing, to 'a Gull,' to 'the intelligence of Thompson,' to 'the knife in the hands of Sir William Fergusson or Spencer Wells of London, or Dr. Graham of this town.' A collection at the end of each lecture is made, to defray expenses. It must be difficult to fix the attention on affairs of the soul when stone and other vulgar physical subjects are under discussion."

At a stated reunion of the Medical Library and Journal Association of New York, held April 18, 1873, Dr. John C. Peters, President, in the chair, the following preamble and resolutions were presented and adopted:

Whereas, This Association has learned of the death of Josiah C. Nott, M.D., a successful and honored physician both in the Northern and Southern sections of our country; therefore,

Resolved, That in the death of Dr. Nott we recognize the loss of one of our most devoted members; a gentleman eminent for his high integrity and his unblemished character, distinguished alike as an ethnologist, gynæcologist, and surgeon, and by his untiring zeal for the advancement of medical science.

Resolved, That, as an expression of our sympathy with his afflicted family, a copy of these resolutions be transmitted to them, and published in the medical journals; also entered on the minutes of this Association.

THE Paris correspondent of the *British Medical Journal* says that "the beautiful collection of books (ancient and modern) belonging to the late Dr. Daremberg has been purchased by the Minister of Public Instruction, and presented to the Library of the Faculty of Medicine of Paris." We believe that the authorities of the London University were desirous of obtaining a part at least of this library for their own shelves.

PRIZES.—The Prix Duval of the Society of Surgery of Paris has been awarded to M. Malherbe for his researches on "The Febrile Condition in Diseases of the Urinary Organs." The Society of Medicine and Surgery of Toulouse proposes as a prize subject for 1874 the following question: "On the purity of the chemical medicines most commonly employed: indicate the most certain and easy tests."

THE PULSE OF VARIOUS ANIMALS.—Vatel, in his "Veterinary Pathology," gives for our domestic animals the following pulse: Horse, from 32 to 38 pulsations per minute; ox or cow, 25 to 42; ass, 48 to 54; sheep, 70 to 79; dog, 90 to 100; cat, 110 to 120; rabbit, 120; guinea-pig, 140; duck, 135; common fowl, 140.

MORTALITY OF PHILADELPHIA.—The interments reported at the Health Office for the week ending April 26, 1873, were 333; 172 adults, and 161 minors. 13 were of bodies brought from the country; making the mortality of the city 320. Among the assigned causes of death were:

Consumption of the Lungs	48
Other Diseases of the Respiratory Organs	45
Diseases of the Circulatory Apparatus	18
Diseases of the Brain and Nervous System	54
Diseases of the Digestive Apparatus	21
Zymotic Diseases (8 from Scarlet Fever)	35
Typhoid Fever	6
Casualties	6
Cancer	5
Exposure	1
Suicide	1
Neglect	1
Debility (including "Inanition" and "Marasmus")	39
Still-born	20
Old Age	11

(The interments reported for the week ending April 27, 1872, were 387.)

THE meteorological record kept at the Pennsylvania Hospital was as follows:

	THERMOMETER. Max.	Min.	BAROMETER. (2 P.M.)
April 20	58.0°	43.5°	30.01 in.
" 21	55.0	41.0	29.94 in. (Rain.)
" 22	49.0	40.0	29.98 in.
" 23	53.0	38.0	30.04 in. (Rain.)
" 24	61.0	42.0	30.01 in.
" 25	58.0	43.0	29.87 in.
" 26	54.0	44.0	30.01 in.

NOTES AND QUERIES.

EAR COUGH.—I have a patient subject to ear cough; a peculiar spasmodic cough being produced by touching any part of the external auditory meatus. Recently I gave him a dose of twenty grains of quinine, which induced a cough exactly similar to the ear cough from external irritation. This cough continued until the influence of the quinine on the system subsided.

J. SOLIS COHEN.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 22, 1873, TO APRIL 28, 1873, INCLUSIVE.

HEAD, J. F., SURGEON and MEDICAL DIRECTOR.—Granted thirty days' leave of absence. S. O. 77, Department of Dakota, April 17, 1873.

HEGER, A., SURGEON.—In addition to his present duties, to perform those of Medical Director of the Department. S. O. 77, c. s., Department of Dakota.

BENTLEY, EDWIN, ASSISTANT-SURGEON.—To accompany Battery "G," 4th Artillery, for service in the field against the Modoc Indians. S. O. 44, Department of California, April 13, 1873.

GIRARD, J. B., ASSISTANT-SURGEON.—Assigned to duty at Camp Apache, A. T. S. O. 21, Department of Arizona, March 31, 1873.

POPE, B. F., ASSISTANT-SURGEON.—Assigned to duty at Humboldt, Tenn. S. O. 76, Department of the South, April 19, 1873.

BOOKS AND PAMPHLETS RECEIVED.

Hand-Book for the Physiological Laboratory. By E. Klein, M.D., Assistant-Professor in the Pathological Laboratory of the Brown Institution, London, etc.; J. Burdon Sanderson, M.D., F.R.S., etc.; Michael Foster, M.A., M.D., F.R.S., etc., and T. Lauder Brunton, M.D., D.Sc., etc. Edited by J. Burdon Sanderson. In two volumes, 8vo. With One Hundred and Thirty-three Plates. Vol. I., text, pp. 585. Vol. II., plates. Philadelphia, Lindsay & Blakiston, 1873.

The Mechanism of the Ossicles of the Ear and Membrana Tympani. By H. Helmholtz, Professor of Physiology in the University of Berlin, Prussia. Translated by Albert H. Buck and Normand Smith, of New York. With Twelve Illustrations. 8vo, pp. 69. New York, William Wood & Co., 1873.

Clinical Lectures on Various Important Diseases: being a Collection of the Clinical Lectures delivered in the Medical Wards of Mercy Hospital, Chicago. By Nathan S. Davis, A.M., M.D., etc. Edited by Frank H. Davis, M.D. Small 8vo, pp. 262. Chicago, J. J. Spalding & Co., 1873.

Archives of Ophthalmology and Otology. Edited and published simultaneously in English and German. By Professor H. Knapp, M.D., of New York, and Professor S. Moos, M.D., of Heidelberg. Vol. III., No. 1, 8vo, pp. 260. Illustrated. New York, William Wood & Co., 1873.

A Hand-Book of Medical Electricity. By Herbert Tibbits, M.D., L.R.C.P. Lond., etc. With Sixty-four Illustrations. 8vo, pp. 164. Philadelphia, Lindsay & Blakiston, 1873.

Fourth Annual Report of the State Board of Health of Massachusetts. January, 1873. 8vo, pp. 473. Boston.

SATURDAY, MAY 10, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE ON ECZEMA RUBRUM.

Delivered at the Dispensary for Skin Diseases, April 4, 1873,

BY LOUIS A. DUHRING, M.D.

Reported by Dr. ARTHUR VAN HARLINGEN.

GENTLEMEN: The patient before you presents one of the commonest, and, because one of the commonest, therefore one of the most important and interesting diseases of the skin which you are likely to meet.

He is a boiler-maker by occupation, of temperate habits, and 41 years of age. His trouble began about six months ago, after he had received a scratch from a nail on the front of his leg. It soon itched, and later became wet and discharged a fluid. At present the limb is painful when he is obliged to stand upon it. Such is the history which we gain from the patient. Now let us see what the appearances are.

We have upon this leg a disease of six months' standing, distinguished by a good deal of chronic inflammation of a certain character. In places the skin is denuded of epidermis,—raw, in fact,—and you can see the corium with the torn apices of the papillæ. On close examination numerous small vesicles, the size of a mustard-seed, can be seen here and there, many of them broken open and torn.

There is, and has been, much itching, and the patient cannot resist the temptation to scratch. I might observe here, however, that in a certain number of cases of eczema rubrum, itching is not so prominent a symptom as in this case, though both itching and burning are the rule.

The general appearance of the diseased skin presents a dusky red color, with the bases of the numerous torn vesicles indicated by bright red points. From the greater portion of the surface there is a continual oozing of a pale-yellowish, sticky, syrupy fluid, which accompanies no other disease of the skin.

After a few hours' application, a bandage or stocking covering this limb will become wet through and through, and then, drying, will become stained a light straw-color, and stiffened as if with sizing.

Over some portions of the limb you will observe that the appearances are different; for here we have no redness, but crusts.

Let us examine closely these various manifestations, and see what we can learn of the history and nature of the affection we are studying.

The direct causes of eczema are various: excessive heat, blows, exposure to the weather, neglect, and dirt, are some of these, and the varied appearances which the disease often presents are in some degree connected with the immediate cause.

In the case before us we see scattered over the surface the vesicles of which I have just spoken. These are the earliest manifestations of the disease, and, as we have seen, they are still making their appearance in some places. These vesicles are the seat of great and characteristic itching, the result of which is that the vesicles are torn open by scratching.

But this is not the only result of scratching, for the epidermis is abraded, and the corium also exposed, from the bruised papillæ of which blood issues forth to color the crusts of dried serum.

Another manifestation which we must not lose sight of in the study of this case is the crusts which cover some portions of the limb.

If you will consider a moment, you will perceive that these crusts are simply the dried serous exudations, which, were the leg altogether neglected, would cover it entirely, but which can always be prevented from forming with proper attention and treatment.

Let me call your attention to a cause of the disease we are considering, in the shape of these varicose veins you perceive over the surface of the leg.

Varicose veins, especially in women, are a frequent cause of eczema rubrum. They are often accompanied by itching, which is most severe when the person is warm in bed, and during sleep the patient will scratch and tear the skin in the effort to get relief. In individuals who have a constitutional tendency to eczematous eruptions this scratching is sufficient to bring on an attack of the disease; and there is little doubt but that these enlarged veins in this man's leg have contributed materially towards bringing on the condition before us.

The disease, as you observe, is confined to one leg. Eczema rubrum is an affection which may or may not be symmetrical in its occurrence; it may attack one limb or both.

We have here, then, a case of eczema rubrum, or, as I prefer to call it, eczema madidans, from the characteristic weeping or oozing of serous exudation.

This affection is not usually self-curable, and if allowed to go on without proper treatment may last indefinitely, the area of disease extending, and the infiltration of the tissues becoming more and more marked. We often see eczema rubrum of the leg of twenty years' or even longer duration. Nevertheless, when taken properly in hand, with an appropriate course of treatment instituted, and the directions of the physician faithfully carried out, the disease is one of the most curable of all skin-affections, and when once cured is not likely to relapse.

Now as regards the treatment. You must remember that this case is one of chronic disease, and that the treatment which is highly appropriate here would not suit at all in an acute eczema of a few weeks' duration. I shall order for this man two to four ounces of sapo viridis and eight ounces of unguentum diachyli.

The former is simply a potash soap, which is manufactured in Germany. The unguentum diachyli is not so well known, and you will find the

formula for its preparation in the University of Pennsylvania Pharmacopœia and in Neumann's Hand-book of Skin Diseases.

The method of using these remedies is as follows:

The affected limb is first rubbed smartly for some minutes with a flannel rag covered with the soap, the rubbing being so brisk as even to make the skin bleed a little. Then, the soap being thoroughly washed from the surface by warm water, and the limb dried by gentle patting—not rubbing—with a soft towel, the ointment is applied, spread quite thickly on strips of soft linen about three inches wide and sufficiently long to go entirely around the leg, thus covering the diseased portion completely.

The effect of the rubbing with soap is at first to cause quite a good deal of stinging and burning, and the leg for the time looks worse than it did before.

The application of the ointment, however, soon soothes the part materially, and great comfort is experienced for the next ten or twelve hours. At the end of that time the itching has set in again, and it is time for a new application of the soap and ointment. You should, if possible, see your patient the very next day after ordering this treatment, in order to ascertain whether your directions have been complied with.

You will almost invariably find that some mistake has been made, for it is rare to find a patient who will at first carry out every detail of the plan, and, unless every thing is done properly, you will not get a satisfactory result.

This treatment should be continued, the rubbing with the soap and application of ointment being made with the same amount of care. At the end of six weeks a very decided change for the better will be observed. The vesicles will cease to form, the serous oozing will no longer be noticed, the congestion and infiltration will have disappeared, and the skin will have once more assumed a healthy appearance.

ORIGINAL COMMUNICATIONS.

CASES OF PARESIS.*

Read before the Northern Medical Association of Philadelphia,

BY A. K. MINICH, M.D.

CASE I.—William Jones, aged 53, American, widower; by trade a butcher; intemperate; common education; was admitted into the Insane Department of the Philadelphia Hospital, November, 1868. He first manifested symptoms of mental derangement about one year prior to his admission, by speaking ill of all he knew, by neglecting to keep himself as clean and neat as was his custom, and by getting up at any hour of the night and opening the doors and windows of his house. Among the first symptoms that attracted notice after his admission were difficult articulation and a staggering gait. These gradually increased until the performance of either walking or talking claimed his whole attention and required the concentration of all his powers. He could not walk and converse at the same time. If interrogated while walking, he would always stop to answer. His walk was peculiar. His feet were widely separated, and raised but slightly. He would take very short steps; to keep his balance demanded special attention. His general sensibility was somewhat diminished; taste and smell to a more marked degree. He could not distinguish between wine and beer. This fact increases in significance when we remember that his previous intemperate habits rendered him quite familiar with drinks of this kind. He would present himself in the morning almost completely covered with his own fæces, and at the same time assert most emphatically that he was perfectly clean. He had no local paralysis of motion. His appetite was good, and often voracious; nutrition seemed to be good, for he bore the appearance of ordinary health. His strength, however, was impaired; pulling his boots on and off was quite a task. His pupils were remarkably small. Thirst always great. He had very frequent attacks of diarrhœa, and his urine was loaded with phosphates. Late in his disease he would never speak unless spoken to. When about to respond to our very frequent salutation, "How are you, Mr. Jones?" there would be the usual play of muscular movements around the mouth, then following in thickened stuttering tones the invariable answer, "*Furshrate*" (first-rate.) We say invariably, for no matter how afflicted, how much prostrated by prolonged diarrhœa or otherwise, such it would be.

On the morning of the 26th of June, 1869, he was found with cold extremities, hurried respiration, and inability to speak above a whisper. There was no motor paralysis. Sensation as usual. His face had assumed the Hippocratic cast. It was evident that life was nearly extinct. On being asked how he felt, he answered, in an audible whisper, "Furshrate." In a few minutes he was again asked; he moved his lips, but I could hear nothing. Bending my head close to his, the question was repeated. He whispered "Fur" with one breath; the other syllable was drowned in the fatal throat-rattle. Poor deluded patient! He believed himself "first-rate" even when the cold damp dew of death was on his brow. A post-mortem examination showed that the immediate cause of death was meningeal apoplexy. On opening his skull, about seven ounces of serum escaped. A blood-clot presenting a large surface displayed itself on removing the dura mater from the upper surface of the brain. It was more marked over the middle lobes. The pia mater and arachnoid were congested and thickened, that portion covering the apices of the anterior lobes particularly so. The gray matter of the brain was atrophied, and somewhat softer than the white portion, which was abnormally firm. Ventricles empty. Septum lucidum thickened. Whole floor of fourth ventricle covered by minute granulations. A supernumerary artery, anastomosing with the anterior communicating, and coursing into the fissure between the anterior lobes, existed.

* See *Philadelphia Medical Times* for December 21, 1872, p. 179.

Case II.—Powell Roberts, aged 40 years; American; single; laborer; temperate; common education; was admitted August, 1868. He was an epileptic since the age of 14 years. The first symptom which attracted the attention of his friends was his disposition to wander from home. At the time of his admission he very often was under the impression that he was engaged in manual labor when in reality he was idle. He would pick at his clothes, tear them into shreds, unite them to form a line, and show by his movements that he believed himself to be on the bank of some stream, enjoying the life of a lucky angler. True to the ambitious nature of every paretic, he always caught "big fish." These symptoms, as well as embarrassed utterance and irregular muscular movements, attended him throughout his disease. His appetite was very good, but he had frequent attacks of diarrhœa. He would pass his urine and fæces in bed, and wallow in them apparently with comfort. Urine very phosphatic. He died April, 1869, in a state of dementia, of exhaustion consequent upon a large bed-sore. Post-mortem examination showed traces of inflammatory change. Pons varolii and septum lucidum were found softened to a marked degree. He had a finely-developed head.

Case III.—Elizabeth Daily, aged 30 years; married; two children; temperate; common education; was admitted August, 1868. Symptoms of disease first manifested by carelessness in household duties. Within the last fourteen months (December, 1869) she has had several attacks of acute mania, the last of which was followed by the never-failing symptom of paresis, *i.e.*, a disposition to boast. Her speech is thick, tremulous, and drawling. Lips quiver. Though a pauper, her wealth and generosity are unbounded. She takes great pride in talking of incidents of her married life, her horses, carriages, colored servants, but more particularly her last confinement. On this occasion she says she gave birth to thirteen full-grown children after being but nine weeks in the "family way." All these were born with long black hair which hung down over their shoulders, and on the instant of their exit jumped from the bed and frisked around the room. This wonderful and copious disgorgement, she tells us, did not cause her any inconvenience, as she was in bed only an hour, and was knitting at the time. She died February, 1871, full of hope and generous impulses.

Case IV.—Frederick Stricker, aged 52; married; four children; tailor; moderate drinker; was admitted June, 1869. Five months prior to this date he began to inquire of his friends whether they considered him a fit subject for an insane-asylum. At the time of his admission, though very poor, he was seriously contemplating making weighty purchases. There was no permanent hallucination. Was suffering at the time of admission from multiple chancres, which he contracted a few weeks before. He always expressed himself as being "first-rate;" laughed heartily, and was in the best of spirits. He was very anxious about his large establishments and his numerous workmen. He feared their families might suffer during his absence. His lips quivered, and his hands were very tremulous, so that his chirography was almost unintelligible. He attempted to work at his trade in the hospital, giving evidence of great confidence in himself, but his work was indicative of marked impairment. I remember a pair of pantaloons that he spoiled by an attempt to produce an alteration in their fit; one leg he narrowed down to encase a broom-stick, the other he insisted must be enlarged. He could scarcely thread a needle. When asked to protrude his penis, his trembling hands would invariably open his shirt-collar. In response to a call of nature to move his bowels, he would search diligently for a chamber, sit upon it without lowering his pants, defecate in his drawers, and then carefully replace the empty pot under his bed. His gait was shuffling. Appetite very good. When asked when he was going home, he would answer according to the time of day the question was put. If before eight o'clock A.M., or after four P.M., he would invariably answer, "At eight o'clock;" if between eight A.M. and four P.M., he would answer with equal certainty, "At four o'clock." These answers were given in tones of positive assurance. He died April, 1870, ten months after admission, of apoplexy.

Case V.—Amelia Noble, aged 37; single; common education; died September, 1869. She presented all the symptoms of paresis throughout her disease, which lasted about two and a half years. She had frequent attacks of epileptic convulsions. Right-sided ptosis existed. Aside from this there was no paralysis. The post-mortem appearances of her brain and skull were very singular and interesting. One-third, rather more, of the right hemisphere was wanting. This was at the expense of the anterior and middle lobe. Upon looking down upon the brain the corresponding side of the cerebellum was visible. The convolutions of gray matter covering this surface were not interfered with. They dipped as deeply as upon the sound side. It appeared as though that portion of the brain had collapsed, or as if the interior white portion had been scooped out, admitting of a sinking of the cortical substance. This space, *i.e.*, between the sunken portion and the skull, was occupied by a sac—the arachnoid—containing one pint of a clear serous fluid. This dropsy was local, owing to the attachment of the arachnoid to the margin of the depressed portion of the brain. The bones in contact with the sac were partially absorbed, rendering the ordinarily obtuse prominences sharp and pointed. The right side of the skull was but half the thickness of the left, and minus the diploïc structure. The grooves for the meningeal vessels were obliterated upon the affected side. The fossa above the right plate of the orbital process of the frontal bone was double the size of the left. Cribriform plate of ethmoid depressed on right side to such a degree as to approximate the crista-galli and orbital plate of left side. The whole of the right half of base of skull bulged out, making the anterior and middle fossa of base of skull half as large again as the left. The bones of the left side of the base of the skull were much more dense than on the right side.

Right lesser wing of sphenoid projecting up, forming a long sharp process. A marked bony prominence existed at the junction of the basilar process of occipital and sphenoid. Carotid and vertebral arteries ossified. Pacchionian bodies wanting on right side, but profuse on left. In their midst was, as a result of inflammation, a deposit of fibrin about the size of a cherry. Similar fibrinous deposits were found scattered over the arachnoid. A deep fossa corresponding to the situation of the Pacchionian bodies existed on the left side. Right lateral ventricle small, containing fluid. Weight of brain, thirty-five ounces.

LIGATION OF THE FEMORAL ARTERY FOR LARGE ANEURISM OF THE POPLITEAL ARTERY—RECOVERY.

BY J. EWING MEARS, M.D.

MAY 14, 1871, I was asked by Dr. J. T. Rowland, of Media, Delaware County, to see in consultation a patient who was suffering from an aneurism of the left popliteal artery. The following history of the case was obtained by his son, Dr. F. F. Rowland, then a student of medicine:

"T. K., æt. 66 years, native of Ireland, temperate, farmer by occupation. With the exception of several attacks of rheumatism, he has enjoyed good health. He has never sustained any injury to which he can attribute the origin of the tumor. The first intimation he had of any trouble in his leg was in September, 1870, when he noticed that in tying the string in the shoe of the left foot a tingling sensation was felt, which extended up to the knee. This condition continued until January 1, 1871, when he discovered a tumor, about the size of a small egg, occupying the popliteal space. At first the growth of the tumor was slow. Within the past two weeks the increase in size has been very rapid, measuring at this date twenty-six inches in circumference."

On examination, a large, irregular-shaped tumor was found occupying the left popliteal space, and encroaching, to a great extent, upon the external surface of the limb. The surface was cold and had the livid hue which indicates venous congestion. Large veins were distinctly visible coursing over it. The leg was flexed at an angle of 60°, and was greatly increased in size by œdema. Pulsation could not be detected, and the aneurismal bruit was distant and indistinct.

During the past two weeks the patient had suffered intense pain from the pressure produced by the rapidly enlarging tumor, and was greatly exhausted by pain and loss of rest. Anodynes in large doses failed to alleviate his sufferings, and he was extremely anxious that something should be done for his relief. A careful examination of the heart and superficial arteries was made, in order to ascertain their condition. This examination showing them to be free from disease, I advised ligation of the femoral artery according to Hunter's method. The plan of treatment being accepted, I cut down upon the vessel, and surrounded it with a large silk ligature, which was applied with moderate force to the artery and was successful in controlling the circulation through the vessel and aneurismal sac. The limb was then enveloped in cotton wool, kept in place by a loosely-applied roller, and half a grain of morphia was given hypodermically.

Under the watchful care of Mr. Rowland, the patient made a satisfactory recovery, the ligature not being detached until the *twenty-sixth* day. The pain was relieved at once, and the tumor slowly decreased in size. At this time, two years after the operation, the measurement about the knee is fifteen inches, and a small tumor about the size of an English walnut occupies the popliteal space. The patient enjoys good health, and is able to perform his ordinary duties about the farm.

Remarks.—The very unfavorable condition of the patient, exhausted by pain and loss of rest, with the character of the aneurism from which he was suffering, rendered the prognosis in this case doubtful under any plan of treatment. The condition of the patient was such as to imperatively demand that relief by surgical treatment should not be long delayed, and at the same time his state, as well as the nature and condition of the aneurism, made the question as to the selection of the method of treatment one of great importance, and one which required most careful deliberation. Treatment by compression, so frequently successful in ordinary cases of popliteal aneurism, did not appear to be applicable in this case, for these reasons: 1. The possibility of failure, and, as a consequence, the continuance of the pain and other unfavorable symptoms. 2. The danger of increasing the œdema and venous congestion, already of a threatening character, in reference to the production of gangrene.

The fact also that there were not at hand proper appliances for making compression had its influence in the decision to reject a trial of this method of treatment,—a matter of importance always; especially does it obtain in such a case as the one under consideration.

Amputation at the middle of the thigh was deemed unadvisable on account of the condition of the patient. The shock consequent upon an operation of such magnitude would have produced, in all probability, a speedily fatal termination.

Ligation of the femoral artery, therefore, while not free from some of the objections properly urged against other methods, seemed to be the plan of treatment presenting the most favorable prospects of success.

The employment of a large ligature, and its application to the vessel with moderate force, without doubt contributed to the successful issue by preventing the too rapid separation of the coats of the vessel, with the hazard of producing secondary hemorrhage.

A GYNÆCOLOGICAL CURIOSITY.

BY JOSEPH R. BECK, M.D.,

Fort Wayne, Ind.

ON the 14th of November, 1872, I was consulted by Mrs. J. H. S. for advice in regard to a variety of symptoms, chiefly referred, however, to the pelvic region. She states that she missed her menstrual epoch, last due on the 12th of October,

a little more than a month prior to the date of the consultation. Inasmuch as a majority of the symptoms pointed decisively towards the existence of pregnancy, there was some difficulty in regard to the diagnosis of the case; but on taking into consideration the fact that the symptoms spoken of seemed to be those due to a *two to three months'* pregnancy, which idea was manifestly to be excluded from this case, I deemed myself to be warranted in making an exploration of the uterus.

For the accomplishment of this purpose I introduced a large-sized sponge tent, which, entering the cervix uteri without the least difficulty, was permitted to remain twelve hours before being extracted. The dilatation of the os and cervix uteri, following the use of the tent, revealed the presence of a good-sized polypous tumor, attached to the fundus of the uterus by a pedicle about one-fourth of an inch thick. The uterus was enlarged by the tumor to nearly the size of a five months' pregnancy, and the polypus filled the cavity almost completely.

By reason of existing circumstances, which could not be satisfactorily controlled at the time, it was deemed best to defer the operation for the removal of the polypus until some time in March following, when her affairs could be arranged more to order. Accordingly, she was temporarily dismissed from treatment, and I did not again see her until Sunday morning, February 23, 1873. In the interim, however, I prescribed for an intermittent with which she was troubled, perhaps two or three times.

On the morning of the date last mentioned I was sent for to see her, and found her suffering from hypercatharsis. She stated that on the previous day, Saturday, at about four o'clock in the afternoon, she had taken four pills from a box labelled "Bragg's Indian Queen Pills," for the purpose of being purged. At seven o'clock in the evening, not having heard from the first four, she took four more of the same pills; and again at half-past eleven, no movement having been had in the mean time, she took the third dose of four more, making twelve pills in all. On Sunday morning, however, she began to be purged violently, the purging being accompanied by a great deal of violent tenesmus and vesical irritation. For this she was ordered sulphate of morphia in half-grain doses, repeated every third hour.

She soon became quiet, and so continued until Tuesday morning, when she began to complain of periodic pains in the pelvic region, very like, in her opinion, to labor-pains. For these she was ordered to resume the anodyne in the same doses; and while she was rendered more comfortable thereby, yet the pains did not by any means cease. I saw her again at noon, but, deeming the matter to be of slight importance, and not having a thought of the polypus in this connection, I made no vaginal examination.

Sitting in my library, just at tea-time of the same day, I was called by the husband of my patient to see his wife in a hurry, as she had had a discharge from her vagina of some "solid body." Upon making an examination, sure enough I found lying just outside the vulva my old acquaintance, the polypous tumor, entire in every respect, save that the pedicle was torn off very close to the body of the tumor. I examined the uterus, and found the remainder of a long pedicle *in situ*, most of which I removed, finding not the least inversion of the uterus present.

Upon gathering up the polypus for removal, I was very much surprised to find lying about a foot from the vulva, and nearly beneath the knees of the patient, a fœtus, entirely enveloped in its membranes, which were unbroken, and with the placenta and cord perfectly intact,—the placenta shaped like and about as large as a fifty-cent fractional-currency bill. The fœtus could not have been of more than four or five weeks' development, and the shape of the placenta, together with the existence of the polypus in utero, determines in my mind the fact that the placental attachment was probably near, if not *in*, the cervix uteri.

That the pregnancy occurred while the uterine cavity was occupied by the polypus, cannot be doubted; and I think I am justified in the conclusion that the placental attachment was very low down indeed. The patient did not lose three ounces of blood in all, and the uterus, responding promptly to the stimulus of ergot, contracted powerfully. The patient made a good recovery in four days from the evacuation of the uterine contents.

15 East Washington St.

EXCRETION OF IODINE AND BROMINE BY THE MAMMARY GLANDS.

BY J. ENEU LOUGHLIN, M.D.,

Philadelphia.

THE excretion of certain chemical substances, whether educts or products of bodies ingested as food or as medicines, by the urine, has been proven by the experiments of Lehman, Gorup-Besanez, Heller, and a host of other observers. A similar set of experiments upon the excretion of substances by the mammary secretion has not, as yet, been fully completed. During the autumn and winter of 1871 and 1872, researches upon the excretion of iodine, bromine, and sulphate of quinine, by the mammary secretion, led to the following determinations:

1. Iodine. Two ounces of milk were obtained from a woman who had for two weeks taken the following prescription:

℞ Potass. iodid., gr. x.,
Syr. sarsap. comp., ℥j. M.
Sig. Three times daily.

The sample of milk was divided into four portions, marked 1, 2, 3, 4. No. 1 was treated with acetic acid gtt. x, gently evaporated to dryness, mixed with two ounces distilled water, and filtered, the filtrate evaporated to dryness, the residue mixed with peroxide of manganese ℥j, sulphuric acid ℥ss, and distilled; the distillate mixed with bisulphide of carbon, ℥ij, and set aside. Color test marked perceptible. No. 2, gently evaporated to dryness, treated with chlorine-water, filtered,

and the filtrate mixed with water and bisulphide of carbon, and set aside for twenty-four hours.

Bisulphide of carbon was more strongly tinged than in No. 1. Comparison yielded color test marked very perceptible.

No 3 was evaporated to dryness, mixed with sulphuric acid and peroxide of manganese and distilled, first, through a tube twelve inches long, one-half inch bore, thence through a Mohr's condenser; both, carefully examined in the direction of their length, showed no violet tinge. Bisulphide of carbon passed through tube and condenser, and mixed with distillate, became tinged after seventy-two hours' exposure; color test faint.

No. 4 was evaporated to dryness, treated with distilled water, and filtered, the filtrate strongly concentrated, and mixed with its volume of solution of nitrate of silver. At the end of six days examined; no precipitate visible.

Similar experiments were performed with milk from a patient taking sixty grains bromide of potassium per day; chloroform being substituted for bisulphide of carbon. Nos. 1 and 2 were successful, No. 3 partially successful, and No. 4 wholly unsuccessful. More time was required to develop bromine tints than iodine; the period of forty-eight to ninety-six hours being required. Alcohol had a very happy effect in hastening the tints.

A RARE CASE OF RESTITUTION OF THE MEMBRANA TYMPANI AFTER FIFTEEN YEARS OF DISEASE.

BY C. H. BURNETT, M.D.,

Aural Surgeon to Philadelphia Dispensary and the Presbyterian Hospital.

ON the last day of July, 1872, Christian L., 15 years old, a German, presented himself for treatment at the Philadelphia Dispensary. His complaint was, that since infancy he has had a discharge from the right ear, with progressive hardness of hearing. He says that there has never been any discharge from the left ear; all of which statements were corroborated by his father, who accompanied him.

My examination revealed the presence of a copious light-green discharge in the meatus. When this was removed I discovered a large perforation in the postero-superior quadrant of the membrana tympani. Hearing-distance for the watch $\frac{1}{4}$ of the norme. Eustachian tube pervious to the current of air from Politzer's apparatus. After cleansing the meatus thoroughly, I introduced ten drops of a strong solution of nitrate of silver, ʒj–fʒj, and ordered him to syringe the ear *gently* three times daily, at home, and after each syringing to instil into the meatus ten drops of a solution of sulphate of zinc (gr. ij–fʒj), allowing them to remain in contact with the affected parts five minutes.

One week later I saw the boy again, and ordered a continuation of the treatment already described, since his condition had greatly improved. By the middle of August the discharge had ceased, and the hearing for the watch had increased to $\frac{1}{2}$ of the norme. On the 19th of August the perforation in the membrana tympani had closed, and the membrane, which at the time of the first examination was swollen and discolored, had assumed the normal shining appearance. The hearing had become relatively normal, *i.e.*, the previously affected ear had assumed a hearing-power equal to that of the unaffected ear, but neither ear was endowed with *sharp* hearing-power, and probably had not been since early childhood. The interesting features of this case are—

1. The length of the duration of the disease.
2. The exquisite restitution of the membrana tympani.
3. The restoration of the hearing.
4. The obvious benefits of the treatment.

127 South Eighteenth Street.

DEFICIENCY OF PECTORALIS MAJOR AND MINOR MUSCLES ON ONE SIDE.—In our issue of April 19 we quoted two reports of these anomalies. Another is put on record in the *Lancet* for March 29, by Mr. John Tweedy, M.R.C.S., who says:

"In January last a muscular young man, aged twenty-three, came under my observation. In examining his chest I noticed a curious deformity resulting from absence of the costo-sternal portion of the pectoralis major muscle, and the whole of the pectoralis minor, and probably also of the upper digitations of the serratus magnus muscle on the right side.

"On making a more detailed examination, the clavicular portion of the great pectoral muscle was found to be somewhat hypertrophied, but the muscles of the back and upper limb were normal. The ribs and sternum were equally well developed on both sides of the body. The right nipple was placed over the fourth rib three and a quarter inches from the mid-sternum, and six inches from the sterno-clavicular articulation; the left nipple was also on the fourth rib, the above measurements being four and a half and seven inches respectively. The circumferential measurement of the chest at the level of the nipples was thirty-five and three-quarter inches, of which the right side took up seventeen and a quarter inches, and the left eighteen and a half inches. The measurement round the right arm at the insertion of the deltoid muscle was ten and a half inches; round the left, eleven and a half. None of the movements at the shoulder-joint were in the least impaired. When the arm was raised, the axillary artery could be felt pulsating immediately under the skin, but in other respects, as far as palpation could determine, the vessel was normal. Although the right arm is very powerful, the man is left-handed; and this may account for the slight difference in the measurement of the two arms. With the exception of an oblique inguinal hernia on the right side, no other abnormal condition could be detected in any part of the body; nor did the man know of any muscular peculiarity in any of his relatives."

Mr. Tweedy refers to analogous cases reported by Poland, Macalister, Quain, and Barkow.

DR. MATTHEWS DUNCAN gives the following rule for calculating the time of expected confinement: Ascertain the day on which menstruation ceased, take that day nine months forward, as two hundred and seventy-five days, and add three days to make up two hundred and seventy-eight, the average time of pregnancy.

THE *Athenæum* states that a substance called ceresine, obtained as a by-product in purifying ozokerite for the manufacture of paraffin, is now used in Vienna as a substitute for bees'-wax in certain medicinal preparations.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 10, 1873.

EDITORIAL.

THE BOSTON DIFFICULTY.

FROM very vague items in the daily papers, our readers have doubtless become aware that certain members of the Massachusetts Medical Society are on trial, charged with practising homœopathy. Exactly what is being done we have been unable to learn by study of the secular papers of Boston; but we believe a court medical is in session, unfortunately with closed doors. This matter is one of no ordinary moment, and it is to be hoped that those having it in charge will proceed with the utmost prudence and judgment. The question, we take it, is as to the right of the adherents of any exclusive dogma to demand the privilege of entrance or of continued membership in a society composed of practitioners of scientific medicine, and their power to compel their admission to such privileges.

If an association such as the Massachusetts Medical Society has the right to frame its own laws, it certainly has the right to decide as to the qualification for membership. If those conditions are infringed by any of its members, it as certainly has the right to expel the offending persons. Should this be denied them, the sooner they dissolve their organization and form a new one, the better.

The fact is that the bigotry and narrow-mindedness are not on the side of the so-called "regular profession," but with those who would exclude, if they could, all practice not based on their own notion. But if it is true that "*similia similibus curantur*," it must be so in all cases, simple or complex, slight or desperate. That this law is not of universal application, or at least cannot be always appealed to by its adherents, is abundantly proved by their own published records. And yet they, hugging their dogma with one hand, and with the other continually gathering experience from "allopaths," who "bleed, blister, leech, and purge their patients to death" (see any number of any homœopathic journal), cry aloud for recognition as brethren from these "old fogies" and "conservatives."

The points in regard to which prudence and caution are especially called for in the conduct of this matter are, the clear showing of the exact difference between honest homœopathy and honestly scientific practice, and of the reasons why the two cannot be made to harmonize, or even to work side by side in any medical organization. There must be no martyrizing of the dogmatists, no shirking of any of their arguments, no stifling of any claims they can sustain. We hope, and are willing to believe, that the business is in safe hands.

ANOTHER LIFE-INSURANCE CASE.

IN our last issue we commented upon a case in which suit was brought against the World Mutual Life-Insurance Company for the amount of a policy, payment of which was refused on the ground that it was obtained by fraud. The jury gave a verdict against the company, but the judge set it aside as contrary to the evidence, and ordered a new trial.

Another case is reported as follows in the *Public Ledger* of May 1:

"The Supreme Court of the United States rendered a decision yesterday in the case of the Mutual Life-Insurance Company of New York *vs.* Ferry. The company had refused to pay the insurance on the life of a person who committed suicide by taking poison. The facts show that the reason of deceased had become 'so impaired by insanity that his suicide was not his voluntary intelligent act.' On these facts the court holds that the company is liable, although the policy contained a provision against suicide."

It certainly seems as if not only the law but the equity of the matter would indicate the justice of this ruling. We are aware that in most if not all life-policies there is a clause making them invalid in case of the suicide of the insured; but this must manifestly be set aside if the act is shown to have been committed while in a state of insanity developed subsequently to the obtaining of the policy. And it is known to be the opinion of some eminent

psychologists that no sane man ever takes his own life; in other words, that suicide is *primâ facie* evidence of unsoundness of mind. Probably upon this ground, it has generally been ruled that suicide did not invalidate policies of life-insurance; and it may perhaps be matter of surprise that any company should contest payment, unless they could clearly show either that the act of self-destruction was committed with full possession of reason, or that the insanity had existed at the time of effecting the insurance.

THE ABUSE OF ALCOHOL.

ONE of the matters with which legislatures have for many years vainly struggled is the regulation of the sale of intoxicating liquors. That a vast amount of suffering and crime may be directly traced to the vice of intemperance, needs no proof. But whether laws can be framed so as to check the evil at that stage,—at the point when it is most difficult to reach it, and when evasion is easiest, as witness the operation, or rather the ineffectiveness, of the so-called "Maine law,"—we greatly doubt.

An easier and, we believe, a more practical way of accomplishing the object would be to make the seller of liquor responsible in due degree for whatever mischief might arise from his traffic. Let the man who knowingly furnishes the means of intoxication to any one already inebriated, or to any one in the habit of drinking, be held as an accessory to any crime committed by his victim, and we are confident there would be fewer instances of such crime. As it is now, a man may prime another for any brutality, and go scot-free; he may see his customer becoming more and more excited, less and less able to control his passions, and still supply him with the maddening poison, knowing that he himself is held blameless for the result.

The great difficulty lies in the influence of the liquor-selling interest to prevent any legislation which would interfere with their trade, and in the opposition of a vast number of voters to any action which would hinder their free indulgence of appetite. And yet we cannot but believe that such protests as the one we print in another column, signed by many of the leading physicians of New York, might be made daily for years, without any appreciable effect on the prevalence of drunkenness, or its legitimate fruit of crime and misery. They are true and just, but they do not touch the evil in its most vulnerable point. Positive measures are of far more value than abstract generalities, in dealing with social abuses.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held April 9, 1873, at 8 o'clock P.M.,

DR. W. B. ATKINSON, PRESIDENT, in the chair,

Dr. J. G. STETLER introduced Dr. J. W. GADSDEN, veterinary surgeon, who then exhibited a number of interesting and beautiful calculi, taken from the alimentary tract of the lower animals; and also made some remarks on a recent case of death in a horse from an "oat-hair" calculus. When the abdominal cavity was opened, the stomach and intestines appeared healthy. On further examination he found a calculus in the colon, just where it makes its second curve across the spine; here it is small in calibre in comparison with the other portion of the large intestine which ends in the rectum. He here exhibited the calculus, and said it was not a true calculus, but one of those denominated "mixed calculus," or "oat-hair concretion." Bad or innutritious provender will often produce this kind in the horse. Thin oats has a considerable quantity of hair at the extremity of the grain, which gives rise to this formation. If by any accident of the horse, as a sudden slip, they be moved from their location, symptoms more or less acute will follow, and often death of the animal, either from mechanical obstruction, or inflammation; sometimes they cause rupture.

Dr. WILLIAM GOODELL opened the discussion on prolapse of the womb by the following remarks:

He divided this disease into three varieties: (*a*) prolapse proper, viz., a substantial descent of the womb; (*b*) prolapse of the cervix from growth of its sub-vaginal portion; (*c*) prolapse of the cervix from elongation of its supra-vaginal portion. In the first variety there is a descent of the whole womb. In the other two, although not essential, there commonly is a greater or less sinking down of the fundus, either from the weight of the cervix or from traction upon it.

The first variety he did not believe to be so rare as stated by late observers. He had repeatedly met with it in old maids, whose vaginas had become relaxed by the absorption of the fat-packing in the pelvis. When the womb is thus deprived of its lower supports, it descends usually in a state of retroversion or of retroflexion.

As an efficient cause of this displacement, great stress has been laid upon the loss of the sigmoid curve of the spine, by the infirmities of age or disease. The axis of the trunk then tends to coincide more and more with the axis of the superior strait, and the brunt of the weight of the intestines is spent upon the womb, which no longer lies under the shelter of the sacral promontory and of the lumbar vertebræ.

In young women, general uterine congestion, perineal lacerations, and the prolonged use of the obstetric binder were common factors in the production of this displacement. The obstetric binder he deemed useful for the first twenty-four or forty-eight hours after labor. For it filled up the void left by the emptying of the womb; it gave a grateful support; it prevented a concealed hemorrhage, and presented a bar to the ingress of air into the uterine cavity. But when kept on for the purpose of preserving the shape, by paralyzing those abdominal muscles which it is intended to strengthen, it not only defeats this object, but crowds the womb down into the pelvic cavity, and, by impeding the freedom of the circulation, impairs the process of involution. In lacerations of the perineum, he always performed the immediate operation, taking care, as advised by Dr. D. H. Agnew, to introduce the first suture some-

what below the lower angle of the rent, and to pass it completely around the wound in order to purse up the tissues and insure perfect approximation.

In the treatment of this kind of prolapse there is no better pessary than Hodge's, or Smith's modification of it. It acts physiologically by restoring the posterior wall of the vagina. Whenever the relaxation of the parts is great, the physician may be driven to the use of the ring pessary; but this should always be deemed a misfortune, as by dilating the vagina it tends to increase the cause of the displacement rather than to remove it. When, as in some old women, the vagina is much shortened, and the vaginal portion of the cervix is obliterated, Cutter's pessary answers an admirable purpose. When prolapsed, a congested womb should be treated not only with a pessary, but also by scarifications, the hot douche, and the usual local remedies.

The second variety of prolapse is rare, at least in a very marked degree. It sometimes results from the traumatisms of labor, or from irregular post-partum involution. It is, perhaps, more commonly a congenital affection. One of its modifications, the conical cervix, is often a cause of dysmenorrhœa and sterility. This form of prolapse needs no treatment unless it interferes with the comfort and the fecundity of the woman. Whenever the cervix is unduly long, it may be amputated; but the conical cervix rarely demands the knife. Dilatation by sponge tents, just before the catamenia, will usually be followed by conception; and parturition completes the cure.

The third variety of prolapse he deemed essentially a hernia of the bladder and vagina. In other words, this condition is due to a primary prolapse of the bladder and vagina, which, by traction on the cervix, draws out the supra-vaginal portion, and which, by impeding the circulation in the sub-vaginal portion, begets an eversion of the os and a hypertrophy of its lips. In this form of displacement, the cervix, by eversion, often resembles the penis of a horse or the snout of a pig. Very commonly, from the exposure to air, friction, and urine, it is the seat of two or more true ulcers, always excavated and sometimes covered by a diphtheritic exudation. The fundus may, or may not, descend very materially; and upon this circumstance will depend the kind of treatment. The sound usually passes in to a distance of at least five inches. The vagina will be found wholly inverted and the bladder greatly prolapsed.

In this form of prolapse pessaries are usually of no avail whatever. They cannot keep up the prolapsed cervix without forcibly bending it almost double, and the pain is therefore unbearable. Whenever the fundus uteri has barely sagged down, a radical cure is attainable by amputating the sub-vaginal portion of the cervix. The suppuration from the open wound sets up the process of involution, and also such alterative changes in the womb as shall cause it to sustain the bladder and vagina *in situ*. But if the fundus is low down or wholly extruded, then, in addition to the ablation of the vaginal cervix, must the vulval opening be contracted by the operation of episio-perineorrhaphy. By combining these two operations he (Dr. G.) had obtained complete success when every other measure had failed even to relieve.

Dr. J. C. MORRIS said that in cases of procidentia he had much faith in mechanical support of the uterus. He usually employs a ring supported by a spiral stem connected with an external wire, bent so as to fit the person, and sustained by a tape passing around the loins. He considered the excision of the os as by no means an easy or trifling operation; severe secondary hemorrhage is apt to occur. Displacement of the womb causes congestion: hence he thought it rational treatment to replace the womb first, and then to treat the congestion. In so doing he had seen great advantage from the use of ergot. In one patient he had observed the uterus reduced from 6½ inches to 3½ inches internal diameter by three weeks' use of iron and ergot. This medication internally, with mechanical support and astringent injections locally, he had found to be reliable treatment. He would inquire of Dr. Goodell as to the relative efficacy and advantage of ergot used hypodermically and internally. Was ergotine used hypodermically different in its action?

Dr. H. H. SMITH could not permit the discussion to close without offering a caution to those advocating excision of the neck, or a portion of the neck, of the uterus. It had been his good fortune in 1839 to follow Lisfranc at the Hospital of La Pitié, in Paris, for six months, and he had frequent opportunities of seeing this operation performed. In most instances the hemorrhage was profuse, and occasionally not controllable even by the actual cautery applied to the cut surface of the uterus, packing of the vagina with charpie and astringents being subsequently necessary; and gentlemen should be careful to watch such cases.

Dr. GOODELL replied, he had purposely avoided using the term *procidentia*, because it had no fixed meaning in obstetric literature. The terms *complete* and *incomplete* prolapse would far better express the degree of displacement. Dr. Morris's case he deemed a typical one of subinvolution, viz., of enlargement of the womb in its totality, and not of the disease under consideration. In his hands the treatment by ergot had also proved very successful, especially when this drug had been administered hypodermically. As to the use of ergot hypodermically, he said experience had proved it of greater efficiency when thus administered; that there was no more prompt method for arresting post-partum hemorrhage; that, following the advice of Hildebrandt, he had recently proved its great value in alleviating the symptoms and reducing the size of mural and sub-mucoid fibroids. The only objections to its use lay in the discoloration of the skin at the seat of puncture, and in the local pain it sometimes gave. The hypodermic dose was from two to six grains of ergotine, or from twenty minims to a syringeful of the officinal fluid extract. He replied to Dr. H. H. Smith by saying that Lisfranc did not use the écraseur or the galvano-cautery, but the knife; further, that in this form of prolapse the supra-vaginal portion of the cervix is so attenuated and wire-drawn that the risk from hemorrhage is not great. The chief danger of the operation he deemed to be possible invasion of the retro-uterine peritoneal fold. This had repeatedly been cut open, but in no reported instance has such accident been followed by death.

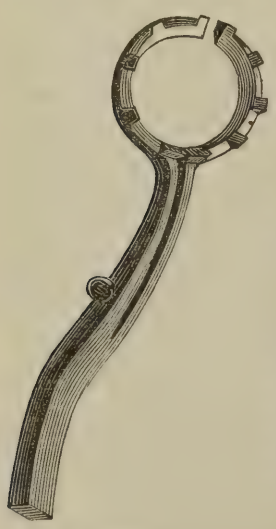
Dr. M. O'HARA remarked that he had no experience in the hypodermic use of ergotine, but would fear the formation of abscess. It has been recommended to be used with caution as an injection in uterine hemorrhage, by reason of the fact that when powdered ergot has been applied to abraded surfaces in the lower animals it has produced sloughing. A German writer is quoted in Hays's *Journal* for January, 1873 (p. 259), as recommending it as very efficacious in tubercular hemorrhages. The solution used is ergotine gr. v to ℥j of glycerine; one-fifth of this being used once or twice a day, and injected near the pectoral muscle. He also mentioned that in one case where he had administered an ordinary dose of morphia for relief of the pain accompanying spinal meningitis, the patient was apparently stricken dead for a minute. He was not narcotized, but shocked. He had also seen alarming sickness frequently follow a hypodermic injection of morphia, without any narcotism. He is not so prone to use it now as formerly. Some deaths have occurred from its use. The variable effects which follow its use

must be attributed to idiosyncrasy. If this be the case we can never be certain. In a case of sciatica, he commenced with small doses of morphia, and increased until he reached as high as one grain, without producing much effect; in the same patient he also used atropia, increasing the dose until he reached $\frac{1}{16}$ gr. This was combined with morphia without any effect. The pain and stiffness disappeared spontaneously at the end of three weeks.

Dr. HALL showed to the Society an instrument for the purpose of fixing the cornea during the little operation of removal of foreign bodies which have become impacted in that structure. Specks of emery, fragments of iron, flying from the chisels of the workmen as they are cutting bolts in boiler-works, and "spalls" (as they are called in laborers' vernacular) of stone, in the operations of the stone-mason, are the daily causes of these accidents. And although the removal of these troublesome guests is generally a simple procedure, still sometimes the "minor" rises to a "major" operation, either from the depth of impaction, the pusillanimity of the patient, or the difficulty of fixation of the globe. The surgeon may take hold of the conjunctiva with a forceps in the fond hope that he has a firm hold of the bulb, and he will find it entirely beyond his control. To obviate this difficulty, Mr. Bader, of Guy's Hospital, invented a forceps with a single sharp "biting" tooth, for the avowed purpose of seizing the sclerotic beneath the conjunctiva, so as to get a firmer "purchase" on the ball, and to prevent giving way or stretching of the conjunctiva.

This Dr. HALL saw, and did not like, as used by Mr. Bader in his clinic at Guy's, in the winter of 1871–72.

Streatfeild's double-pronged forceps, which is really two forceps in one, and is like giving one an extra hand, Dr. H. had always found a great comfort in these troublesome rolling eyes. But this instrument seemed to him to be superior to anything that he had seen, and he only wondered that no one had thought of it before.



It is merely a ring to surround the cornea; a few dentated processes bed themselves in the pericorneal conjunctiva, and thus hold the bulb. It was made by his friend Dr. WM. J. DAVIDSON, of Staunton, Virginia, who was present as a visitor to the Society. The doctor was house-surgeon to the Wills Ophthalmic Hospital in 1855, and his residence there gave him a taste for ophthalmic matters, and served to keep up his interest therein after he had settled in his beautiful mountain home. From his known familiarity with ophthalmic affairs, he was called upon from all around the country-side, to remove foreign bodies from the eye; and, to secure the bulb, he bethought him of some improvement of the fixation-methods now in vogue. This little implement is the result of his cogitations. Not having an instrument-maker at his elbow, he was forced to be his own workman. It is made of hard rubber, cut, shaped, and smoothed with a penknife and sandpaper. The only part of it not the work of the doctor's own hands is the little metal screw to expand or contract the circle; and this was made by the village watchmaker. The hard rubber is not so unpleasant to the eye as "cold steel," and the little projections on the disk sink into the conjunctiva and hold the eye gently but with complete steadiness.

Dr. MCREAN asked what was the best method to treat hemorrhoids occurring during pregnancy. A patient now under his care was within three weeks of her confinement, and had suffered from severe hemorrhage. The piles gave her extreme pain, which he had relieved by the use of an unguent containing gallic acid and morph. acetat.

Dr. SMITH, in reply to Dr. MCREAN, stated that he could not suggest anything more than the usual treatment, as ice applied on a towel after the piles were reduced, or the use of a hemorrhoidal truss, or a firm compress with a T bandage, or a rectal bougie. Such hemorrhoids usually disappeared after delivery. While he had the floor, he would call the attention of the Society to the frequency of the secondary effects of opium, especially the nausea and prostration some hours after the use of morphia either by the skin, mouth, or anus,—and stated that a prominent druggist had recently told him that other physicians had complained of the same result. As it was possible the market was not supplied with so good an opium as formerly, he wished to obtain the experience of any of the members present on this question.

Dr. GOODELL said he had never seen any danger from the bleeding of hemorrhoidal tumors. If the remedies suggested by Professor SMITH should fail, he would recommend the doctor to rupture the sphincter ani.

REVIEWS AND BOOK NOTICES.

CLUB-FOOT: ITS CAUSES, PATHOLOGY, AND TREATMENT. Jacksonian Prize Essay for 1864. By WILLIAM ADAMS, F.R.C.S. With one hundred and six Wood Engravings, and six Lithographic Plates. Second Edition. 8vo, pp. 464. Lindsay & Blakiston, 1873.

We take pleasure in calling attention to this work, as one of the most recent, and one of the best, if not the best, upon an important but too much neglected subject. No class of deformities requires more careful and judicious treatment and closer watching, as well as a more definite course of management in all respects; and yet the diversity of views as to the treatment of club-foot, whether by mechanical or cutting operation and immediate or subsequent extension, is certainly remarkable.

The natural resource to the practical mind under such a conflict of authority must necessarily be an appeal to experience; and this we believe is coming more within the reach of American practitioners, through the instrumentality of public benevolence in the establishment of special hospitals.

The actual necessity for special hospitals for the treatment of those suffering from bodily deformities has been so little felt, that it has been only within a comparatively short time that such institutions have been established in this country. Not only has an increasing interest been manifested during the past few years in the treatment of deformity already existing, but more attention has been directed towards the prevention and arrest of diseases which are generally followed by deformity. In London, besides the three great Orthopædic Hospitals, there are also special departments for this branch of surgery established in St. Bartholomew's and St. George's Hospitals.

It is well known that operative surgery is of but little avail, in many of the cases of deformity, unless in the

after-treatment we can have, in addition to the proper mechanical appliances, all such physiological adjuvants as may be obtained in the arrangements and exercises of a well-constructed gymnasium,—this combination being often indispensable to a complete restoration. It is easy to understand, therefore, how the deformed poor have but few opportunities for securing the full benefits of treatment, unless aided by special institutions.

An extended notice of the work before us is out of the question, but some of the leading practical points presented may be briefly considered. The history of club-foot and subcutaneous tenotomy is followed by a chapter on the reunion of tendons, with a comparison of the merits of tenotomy and mechanical extension in the treatment of these deformities.

Delpech, after dividing a tendon, allowed the parts to remain in undisturbed apposition, and resorted to extension only after union had taken place; while immediate extension was recommended by Syme. Mr. Adams, in referring to the great difference of opinion on this subject, states, very truly, that English surgeons generally adopt the practice of Delpech, Stromeyer, and Little; while in America immediate extension is generally practised. Some discourage immediate extension, fearing non-union of the divided cord; an accident which we have never observed. Mr. Adams reports only one example; which, however, resulted "from the division being performed immediately behind the inner malleolus,—a situation which orthopædic surgeons never select, but rather always avoid, for the performance of the operation." When tendons are divided on account of a recurrence of deformity, adhesions more or less dense are found; so that as a rule but little gain is effected by such divisions; while the free motion of the joint is materially lessened. "When recontraction of the foot takes place," says Mr. Adams, "and the deformity returns at a distant period after tenotomy, this does not depend upon absorption of the new material, but upon structural alterations taking place in the muscular tissue."

Chapter III. gives the relative merits of tenotomy and mechanical extension, and includes, also, the restoration of form and function; and "a judicious combination of the operative, mechanical, and physiological means" is insisted upon in the treatment of talipes.

The rules for determining when an operation for club-foot is required are given as follows:

1. "When the foot cannot be fully everted, or be brought to a straight line with the leg, by manipulation, and when in the attempt to accomplish this the inner malleolus does not become prominent."

2. "When the os calcis either cannot be depressed at all, or only to a slight degree, or when after the partial eversion of the foot little or no flexion of the ankle-joint can be obtained."

In the treatment of non-congenital spasmodic and paralytic talipes, we agree with Mr. Adams in the opinion "that great benefit may be derived from operative and mechanical treatment, followed by a long course of shampooing and special muscular exercises."

Infantile paralysis, our author believes, has a "marked tendency to spontaneous cure; in slight and moderately severe cases affecting single muscles or groups of associated muscles, complete recovery is the rule; when this fails, great improvement occurs, with very few exceptions." Such is not the clinical history of the cases we have been accustomed to observe. In some the power was regained in a very short time, but more frequently there is a more lingering paralysis, partial or complete. In the treatment of these cases tenotomy and mechanical means are required, especially in the consecutive deformities which so often arise, and which "are produced by adapted atrophy of certain muscles, principally the opponents of those which have suffered paralysis," and which do not result from any active contraction of these muscles.

There is no mention made of the treatment of these cases with electricity, which we believe to exert, in most instances, a marked beneficial influence.

In decided paralysis of the extensor muscles with talipes equinus (in which case the tendo-Achillis alone requires division), Mr. Adams cautions the operator not to use any extension until union has occurred, lest a pes calcaneus should result.

The history of talipes varus, including the congenital and non-congenital varieties and treatment, covers more than one-third of the volume, and is very complete.

In infants, when an operation is required, Mr. Adams directs that this should be done, if the child be in good health, about the second month; so that the cure may be completed before the commencement of dentition. In severe cases of varus, which is always more or less associated with a certain amount of equinus, the author, we are very glad to find, strongly insists upon the operative treatment being divided into two stages.

"The great practical point," he tells us, "is to overcome the inversion of the anterior portion of the foot, to convert the varus into equinus, and afterwards to divide the tendo-Achillis when only the equinus remains."

The attempt is very frequently made to restore a foot to its proper shape at once by force, after division of all the contracted tendons, including the tendo-Achillis. In such cases, however, more or less equinus remains; and if a second or third division of the tendo-Achillis be performed, little or no good is accomplished, and the foot is apt to be rendered much more rigid than before. Continual stretching and manipulation will generally in such cases accomplish more than any division of tendons or tissues.

When on the subject of relapse in cases of varus, we are told that "too much stress can scarcely be laid on the importance of careful attention to the after-treatment, especially as to the employment of mechanical supports acting as a retentive apparatus during the time required by the bone and ligaments to adapt themselves to the normal position of the foot, and also to the improvement of the muscular power by active and passive muscular exercise, shampooing, etc."

Various forms of mechanical appliances adapted by Mr. Adams and others to the different kinds of talipes are described and exhibited; some of them being only passable illustrations. We do not think these appliances compare in simplicity and convenience with the ordinary laced shoe, furnished with lateral screw movement for the foot, with flexion and extension such as have been perfected by the mechanicians of Philadelphia.

That there is considerable prejudice, not so much in the profession, as with the public generally, regarding the division of tendons, cannot be denied. This is in a degree but too well founded. A neglected or badly-treated club-foot, after tenotomy, is sure to produce a worse condition than the previous infirmity. We would be glad if we could never hear of cases of club-foot having been operated on and then immediately consigned, with a mechanical apparatus and a few simple instructions, to the care of friends, as if the cure were already accomplished.

Some of the worst results we have ever seen have been cases operated on where no after-care had been given to the patient. The stubborn facts of successful results are required to convince some that tenotomy is ever needed, and just such books as that of Mr. Adams, exhibiting the results of proper treatment, are invaluable in bringing about the needed change in feeling, while they are at least equally useful in extending

the knowledge of such treatment in a most practical manner.

A Nomenclature of Diseases, with the Reports of the Majority and of the Minority thereon. American Medical Association, Philadelphia, May, 1872.

This is a judicious revision of the names of diseases —a revision which the advance of science rendered imperative. The scientific names ought, perhaps, to have had precedence, as in botany and zoology, and as they are given in England.

Such names need not in all cases be based on pure Latin or Greek, but they may be Latinised or Greekised forms like the hybrids *scarlatina* and *potassa*, or translations like *febris flava*. Words which admit of it may be anglicised, such as *acute, chronic, osteoid, puerperal, abscess, congestion, hysterics, epilepsy*, and even *fever, dropsy, rickets*, and English words like *measles, glanders, plague*, may be used. Nevertheless, Latin forms should be preferred, as in No. 108, where "teething" should be *dentition* to correspond with *dentitio*, as "dentigerous cyst" (No. 79*c*) corresponds with *cystis dentigera*. For the same reason, in Nos. 59*d*, 67, 208, 226, 342-3, "fatty" (degeneration, etc.) should be *adipose*; "aneurysma ex vulnere" (No. 234) should be *an. traumaticum;* and where "coarctatio" is translated "narrowing" (228) and "contraction" (242), the latter should be preferred.

Binary names should be in the same language, yet we have the half-Greek half-Latin form "apoplexia pulmonalis" (291) beside the correct one "phthîsis pneumonica" (298); and in the English versions we find "pneumonic phthîsis" (298) and the hybrid "pulmonary apoplexy" (291), along with "abscess of the lung" (287) and "gangrene of the lung," where *pneumonic apoplexy, pulmonary abscess*, and *pneumonic gangrene* would have been better. In No. 21, "cretismus" should be *cretinismus*, to show the root. In 68*a*, for "eberneus" read "eburneus." In 64, 68, etc., *nucleate, cancellate, aculeate*, etc., are better than "nucleated," etc. "Keloid" (No. 75 and 501) refers to a tumor, and "cheloid" to a tortoise or to claws. No. 321 should be "anthracosis;" No. 520*f* omit "ricinus," as there are various species; and add "lectularius" to 520*h*. In 78*i*, "gelatinous" is better than "glutinosa," but both should give way respectively to "colloid" and "collodes," since hybrids (including forms like scrofulosis) should be avoided when possible. The "ptyalism" (87) of Arum triphyllum, etc., should not be overlooked. "Oidium," on p. 9, should be Oïdium (o-id-i-um).

Critics are beginning to drop the *h* of *rrh*, and the corresponding aspirate of the second *r* in the Greek originals of words like cirrhosis and scirrhus.

The English Magazine of Natural History and the Journal of the Boston Society of Natural History introduced accentuals to indicate the pronunciation,—a plan which, for obvious reasons, in this country, should be introduced into such lists. The usual mode is to indicate long accented syllables with the grave accentual (ˋ), and short ones with the acute (ˊ), as in neuròma, plethòra, prurìtus, entéric, oídium. There is a tendency to pronounce certain words with the î of *marine*, according to the Latin and Continental mode, of which impetîgo, scarlatîna, nephrîtis, and phthîsis are examples.

The two Reports agree essentially, inasmuch as the majority of the Committee present the result as provisional, while the minority desire sufficient delay to get the opinion of the profession upon it.

The above notice is based on the earlier matter of the Report, the rest not having been examined by the reviewer; but it is believed to be sufficient to give the reader an idea of the character of the changes which, to the writer's mind, will be necessary to produce a scientific nomenclature.

Clinical Lectures on Various Important Diseases: being a Collection of the Clinical Lectures delivered in the Medical Wards of Mercy Hospital, Chicago, by Nathan S. Davis, A.M., M.D., etc. Edited by Frank H. Davis, M.D. Small 8vo, pp. 262. Chicago, J. J. Spalding & Co., 1873.

These lectures have been from time to time published in the columns of the Chicago *Medical Examiner*. They belong to a class of literature which has great value, especially for the young practitioner and for those who have few opportunities of seeing collected cases. A very wide range of subjects is embraced,—continued fever, pulmonary tuberculosis, eruptive diseases, intestinal and uterine irritation, summer complaints of children, dropsy, brain and nervous affections, cutaneous diseases. For the most part, these topics seem to be handled in a practical and suggestive manner; but our author's physical science seems to us to be rather behind the age, as witness his remarks on "caloric," at p. 151.

We regret to note also that he has wrestled in vain with the art of prescription-writing,—English and Latin being freely mingled in almost every instance, in a manner offensive to the scholarly eye and unworthy of a professor.

OBITUARY.

Dr. R. Cresson Stiles, who died in West Chester, Pennsylvania, on the 17th ult., in the 43d year of his age, was a graduate of the Medical Department of the University of Pennsylvania, and had studied much abroad. He was, for several years, Professor of Physiology in the Berkshire Medical College, at Pittsfield, Massachusetts. During the war he served very acceptably as a Surgeon of Volunteers. Subsequently he resided for the most part in Brooklyn, and, we believe, was connected with the Long Island College.

Brevet Brigadier-General Madison Mills, Surgeon in the United States Army, died at his quarters at Governor's Island, New York, April 28. Surgeon Mills was a very meritorious officer. He entered the service, according to the date of his first commission, on the 16th of February, in the year 1847. He was promoted to the rank of lieutenant-colonel by brevet on the 29th of November, 1864, and advanced at intervals since to colonel by brevet and brigadier-general by brevet. His remains were interred from the chapel, Governor's Island.

"Colonel Jeff. C. Davis,

"Headquarters, Department of the Columbia, Portland, Oregon.

"At a meeting of the officers serving with the troops operating against the Modoc Indians, the following preamble and resolutions were unanimously adopted:

"*Whereas*, The Almighty has, in his pleasure, removed from among us our late companion and brother-officer, Assistant-Surgeon Thomas McMillin, United States Army, Medical Director of expedition operating against Modoc Indians, who was endeared to us by his uniform kindness, amiability, and many noble qualities, and, whereas, it has come lately to our belief, that while suffering from a disease contracted from exposure in the service, he has nobly and without hesitation performed all duty required of him, both in camp and in the field, and at last become its victim when in face of the enemy: therefore be it

"*Resolved*, That while we greatly deplore his early death, and look upon it as a great loss, not only to ourselves, but to the army at large, and the profession of

which he was a member, and to which he was an ornament, we entertain the hope that his gain is beyond our ability to express.

"*Resolved*, That we take this method to make known and extend our heart-felt sympathy to his family and relatives in their sad bereavement.

"*Resolved*, That a copy of these resolutions be sent to the relatives of our deceased comrade, the *Army and Navy Journal*, *Louisville Courier-Journal*, and *San Francisco Alta*, for publication.

"Ed. R. S. Canby,
"Brigadier-General, President.

"Arthur Cranston,
"First Lieutenant 4th Artillery, Secretary."

The above was received with the autograph signature of General Canby, who has himself, since it was mailed, entered into a personal experience of that which is to him also a "gain beyond our ability to express."

C. H. Crane,
Assistant-Surgeon-General, U.S.A.

Surgeon-General's Office,
Washington, D.C., April 28, 1873.

GLEANINGS FROM OUR EXCHANGES.

On Post-partum Dietetic Treatment. — Dr. Thomas Cairns, in an article published in the "Transactions of the Edinburgh Obstetrical Society," lays down three rules of diet, viz.:

1. "The diet should be nutritious in point of quality.
2. "It should be small in quantity and frequently repeated.
3. "It should be varied in kind and form."

He says of the usual low-diet system, "Such treatment, I humbly maintain, is utterly inconsistent with the principles of obstetrical pathology. I wish I had time to inform the younger members of the Society the real meaning of the term *labor*, because I am certain, if they knew what it actually expresses, they would at once perceive the necessity, on purely pathological grounds, of *feeding* and not *starving* their puerperal patients. . . . Consider the waste of tissue to which the woman is subjected during her confinement, and you must see that unless that waste be supplied by proper and fresh materials, the patient's strength must necessarily be very much reduced below its normal condition; and should any untoward event happen to her in these circumstances, the prognosis must essentially be infinitely more unfavorable than if her system had been duly sustained by generous diet. On these grounds I have always been in the custom of liberally administering to my puerperal patients the most nourishing food which their circumstances enable them to procure, such as soft-boiled eggs, beef-tea, soups, chops, steaks, tripe, etc., with a glass of wine daily in addition, or, if the patients prefer it, a glass of ale or porter; and this treatment, I humbly aver, is based on sound pathological principles. . . . Let the food be administered in small quantities at a time, and at such intervals as shall have insured the complete digestion of the previous diet. . . . Common sense seems to suggest that, with the view of stimulating the appetite and imparting to the patient a positive relish for food, every advantage should be taken of the culinary art in dressing the same article in different forms, and when these have been exhausted, that one article should be substituted for another during the whole period of convalescence."

On the Medicinal Use of Green Soap (*American Journal of Pharmacy*, May, 1873).—The editor, Mr. J. M. Maisch, says, "A short time ago, a correspondent asked us for a formula for tinctura saponis viridis composita, which he informed us was used in the Eastern cities. At first we were unsuccessful in our endeavors to comply with the wish of our correspondent, until Messrs. William McIntyre and Gustavus Krause furnished us with the following formulas, which we publish below for the benefit of our readers.

"Commercial soft or green soap is usually made now, wholly or in part, from common whale and other fish oil. Hempseed oil, or rather a mixture of it with various other liquid fats, has formerly been used, but long since substituted by almost any refuse oil which, on account of smell, rancidity, or color, is unfit for other uses. These oils are saponified with caustic potash, and the desired green color is imparted by blue, green, or yellow pigments, as may be required. Frequently, however, soft soap is met with of a blackish, or rather of such a dirty color that it is difficult to distinguish a particular tint. The soft soap of the London Pharmacopœia of 1851, and of the Edinburgh Pharmacopœia of 1841, was directed to be made from olive oil and potash.

"Green soap is mainly used in medicine for the cure of itch, and in various other skin-diseases, but, on account of its caustic nature, is not often applied.

"The following formulas have been furnished to us:

"*Lotio Saponis viridis* (Prof. Hebra).—Green soap ℥j, boiling water Oj, oil of lavender ℥ss. Mix.

"*Spiritus saponatus kalinus* (Prof. Hebra).—Green soap 2 parts, 95 per cent. alcohol, 1 part. Scent ad libitum.

"*Tinct. Saponis vir. cum pice* (Prof. Hebra).—Green soap, tar, alcohol, equal weights of each.

"*Tinct. Saponis vir. comp.* (Tilbury Fox).—Green soap, oil of cade, alcohol, āā ℥j, oil of lavender f℥iss. Mix."

Precautionary Measures in Amputations and Disarticulations (Petersen, of Kiel: *Berl. Klin. Wochensch.*, 1872, No. 31; quoted from *Centralblatt f. Med. Wiss.*, 1872, No. 39).—The author reports two cases of disarticulation of the hip-joint: the first of which, performed in a case of periostitis and osteomyelitis of the right femur, ended in death.

Four rules are laid down to be followed in these dangerous cases, and experience has taught the author that they are of great service:

1. A firm bandage must be applied to the limb about to be amputated or disarticulated, in order to empty it of its blood, and render the loss of blood as small as possible.
2. An anterior cutaneous flap is to be made, and the vessels should be ligated *en bloc* before the remaining soft parts are cut through.
3. The bone should be sawed through close below the trochanter, after the soft parts are cut, and the remainder of the bone is to be exarticulated by means of a lateral incision after the cessation of the hemorrhage.
4. If the patient has no fever, his blood may be caught and preserved for purposes of transfusion. In case of fever on the part of the patient, blood from another person should be instantly injected into the *vena cruralis*.

Curious Monstrosity.—Dr. T. O. Reynolds, of Kingston, New Hampshire, records, in *The Clinic* of April 19, a case of miscarriage at four months, in which there were two fœtuses expelled, one *in the mouth of the other, its head in the pharynx, its left arm protruding through the left nostril, and its legs hanging out.* There was but one placenta, connected with the larger fœtus.

Vermicular Action of the Urethra Inwards (*British Medical Journal*, March 1).—Dr. Macnamara, at a meeting of the Surgical Society of Ireland, said that for many years he had held (as, indeed, he had been taught) that foreign bodies lodged in the urethra had a tendency to be thrust forward. But, on inquiring more closely into the matter, he was led to believe in the existence of a vermicular action in the urethra, acting from without inwards on a body presenting a sufficiently large superficies. A calculus was thrust forward by the *vis a tergo* of the urinary stream, which overbalanced the vermicular action, as the latter had only a small surface whereon to act. But a catheter, when left in the urethra, had a tendency to pass towards the bladder, and to prevent it from doing so it was often necessary to apply a jugum. The object of this vermicular action was, clearly, to prevent leakage from the bladder. In the volume of the *Dublin Hospital Gazette* for 1858, Mr. Fleming had spoken of a sucking power, or vermicular action, of the urethra, in certain cases, but no mention was elsewhere made of this physiological property of the part. The president remarked that the number of cases where portions of catheter found their way into the bladder strongly confirmed Dr. Macnamara's interesting and novel remarks. Mr. Stapleton could not recognize the existence of any urethral vermicular action, and he believed that an entire catheter never yet had passed into the bladder. Dr. H. Kennedy referred to an example of this accident recorded by Mr. Stokes in the first number of the *Irish Hospital Gazette* (January 1, 1873).

A Test for Epilepsy.—Dr. C. B. Radcliffe, in a Croonian Lecture published in the *Lancet* for April 12, on cerebral exhaustion, mentions epileptiform symptoms as among its phenomena, and says:

"The immediate precursor of the perfect form of the paroxysm is a sign which is somewhat difficult to catch,—corpse-like paleness of the countenance. Delasiauve was the first to notice this phenomenon. Trousseau insists upon it as a mark which distinguishes true from feigned epilepsy. 'Il est une signe,' he says, 'qui se produit au moment de la chute, qui n'est imitable pour personne, c'est la pâleur très-prononcée cadavérique, qui couvre pour un instant la face épileptique. Nous ne la voyons pas, parceque nous arrivons toujours trop tard, alorsque la face est déjà d'une rouge très-prononcée.' And I can fully corroborate the correctness of these statements. In fact, the general form of the epileptic or epileptiform paroxysm, the *haut mal*, begins in the same way as the partial form, the *petit mal;* for it is allowed by all that cadaverous pallor of the countenance is the initial symptom in cases of *petit mal*. Moreover, I can testify to the existence of a corresponding pallor at the same time deep down in the eye, for on several occasions, while happening to be examining the eye with the ophthalmoscope when an attack of *petit mal* has come on, I have seen the pupil dilate and the vascular blush in the fundus become quite pale."

Local Employment of Chlorate of Potash in Cancerous Sores (*Lancet*, April 12).—In the *Berl. Klin. Wochenschrift*, No. 6, 1873, Dr. Burow, of Königsberg, advocates the local employment of chlorate of potash in the treatment of cancerous sores. His proceeding consists in sprinkling the sore with chlorate of potash in powder or crystals, and covering the whole with a wet compress. As the crystals of chlorate of potash exert a more powerful action than the powder, and excite greater pain, Dr. Burow uses the powder first, and replaces it by the crystals when sensibility has been abated. One of the cases was a cancerous sore of the left arm, which healed completely after eight weeks' treatment. Three other cases were cancerous sores of the breast; one was lost sight of, the other two are under treatment and healing well. The fifth case recorded was connected with a cancer which originated in the periosteum of the upper jaw and left cheek-bone, and then became ulcerated; in this case healing was complete in three months.

Miliary Tubercle in Cats.—The occurrence of miliary tubercle in the feline race has been described by Bollinger in *Virchow's Archiv* (vol. lv.). He found, in two female cats, that both lungs had scattered throughout their substance a large number of miliary and submiliary granulations; there was also lobular hepatization, but no cheesy transformation. In one of the animals the left kidney was the only other organ affected; in the other, both kidneys, the liver, and the pancreas contained miliary tubercles. Microscopic examination showed a complete identity between the tubercles found in the cat and those met with in man.

MISCELLANY.

We clip the following items from the daily press:

"Leucocythæmia.—Hon. James Brooks, now lying ill, is affected by symptoms of an obscure disease known as leucocythæmia, or a superabundant development of the white corpuscles of the blood over the red. This conclusion was arrived at after an examination of the patient by eminent physicians of Norfolk, Virginia, and New York. To test the matter thoroughly, specimens of blood were recently taken from various parts of Mr. Brooks's body, and submitted to Dr. J. J. Woodward, of the United States Army Medical Museum. This gentleman subjected the specimens to examination under a most powerful microscope, and reports that the blood is in a disorganized condition, there being an unusual proportion of the white corpuscles, but not in a sufficient quantity to justify the designation of decided leucocythæmia."

[Mr. Brooks died a few days after the above appeared, and a post-mortem examination disclosed extensive cancerous disease of the stomach.—Ed.]

"A most singular banquet has just taken place in Paris. M. Decroire invited several of his friends and a small company of scientific men to dine upon the flesh of horses which had died from the glanders; of cows the victims of the rinderpest; and of an ass just killed for hydrophobia. It was a 'test banquet,'—one that proved the devotion of each man there to science, in that he was willing to risk his life to demonstrate, in the most practical manner, that the flesh of animals is not affected as human food by even the worst diseases."

"A well drawn-up statistical table," says M. Michel Chevalier, "is like an impassive witness, alike above intimidation and seduction; which one can adduce and interrogate with confidence and profit, whenever light is needed upon the various aspects of civilization; for there is hardly one of these which does not manifest itself by tangible facts, and which therefore may not be placed more or less exactly in the legitimate circle of its bearings."

Unlawful Disposal of Infants.—*The British Medical Journal* says, "The Home Secretary has, we understand, directed a special inquiry into the circumstances connected with the late discovery at Bethnal Green of an attempt to bury the bodies of four infants in the coffin of an adult. Such outrages are, it must be feared, not uncommon, although they only occasionally come to light, owing to the absence of any power enabling the authorities at cemeteries to open coffins which they suspect to contain more than one body. Mr. Stansfeld promised the deputation of the Parliamentary Bills Committee of the British Medical Association, which waited on him on Saturday last, that he would attempt to devise clauses for the Registration of Births and Deaths Bill which would carry out a suggestion of Mr. Ernest Hart, and would check the facilities now enjoyed by sextons and undertakers for disposing of bodies of infants without certificate or formality, on the uncertified and unregistered allegation that they were still-born. Such clauses would be very useful, and they will be looked for with interest. No complete check will, however, be given to these practices by any other measure than one requiring the registration, for the purposes of burial, of all infants viable at birth, whether born alive or dead. The coroner for Central Middlesex, Dr. Lankester, writes to us, 'A few months ago, I held an inquest on three or four children found in the roof of a house. One was twelve months old, and another was four months old. These were children taken to an undertaker to be buried as still-born. He received the fees, and, instead of burying them, had stowed them away. There was a long inquiry, but no notice was taken of it by the press.' The test of viability adopted in the clause presented to Mr. Stansfeld by the joint deputation of the Obstetrical Society of London and the Parliamentary Committee of the British Medical Association was an arbitrary one, but one which has received the assent of practical authorities generally; and the adoption of such a clause would prevent a good deal of crime, carelessness, neglect, and outrage of propriety, by the careless disposal of infant bodies which now goes on."

Regeneration of the Eyes in the Crab.—M. Chautran, at a late meeting of the Academy of Sciences of Paris, read a paper stating the results of his interesting investigations upon the regeneration of the eyes of the crab, made in M. Coste's laboratory. If the eyes be excised in a crab of one year old, captured in August, just after moulting, they are completely restored, the new ones assuming the normal form and functions. If, however, the operation be performed in one taken in the month of May, before moulting, this process interferes with their due development, and they are regenerated of an irregular form and size. In adults the new organ is very imperfect.

The American Public Health Association closed its session, at Cincinnati, on May 3. It will meet again on the second Wednesday in September next, at Providence, R.I.

The following medical declaration concerning alcohol has been published in the *National Temperance Advocate*, over the signatures of Drs. E. Delafield, Willard Parker, Alonzo Clark, E. R. Peaslee, C. R. Agnew, Stephen Smith, A. C. Post, Elisha Harris, E. Eliot, Stephen Rogers, Andrew H. Smith, J. R. Leaming, and other New York physicians:

"In view of the alarming prevalence and ill effects of intemperance, with which none are so familiar as members of the medical profession, and which have called forth from eminent English physicians the voice of warning to the people of Great Britain concerning the use of alcoholic beverages, we, the undersigned members of the medical profession of New York and vicinity, unite in the declaration that we believe alcohol should be classed with other powerful drugs; that when prescribed medicinally it should be with conscientious caution and a sense of grave responsibility.

"We are of the opinion that the use of alcoholic liquors as a beverage is productive of a large amount of physical disease; that it entails diseased appetite upon offspring, and that it is the cause of a large percentage of the crime and pauperism of our cities and country.

"We would welcome any judicious and effective legislation — State and national — which should seek to confine the traffic in alcohol to the legitimate purposes of medical and other sciences, art, and mechanism."

Hired Nurses the Best.—Dr. S. Weir Mitchell, in a recent article in *Lippincott's Magazine*, says most truly, "What you want in the sick-room is a calm, steady discipline, existing but unfelt; the patient, cool control which a stranger is far more apt to exercise than a relative. In a word, just as a doctor feels it unwise to attend alone his own dear ones in grave illness, for like but lesser reasons, the best nurse is a stranger,—one who is naturally free from worry and irritation, who is unmoved by traditions of love, and who, acting purely and simply from sense of duty, takes that care of her own health which is essential to make her nursing perfect. Such an attendant is willing to take her share of sleep and fresh air, and so remain cool and tranquil under all circumstances and in all exigencies, making far more light the task of the doctor, and able from experience of illness to note changes and call for aid at needed times. Such help excludes from the sick-room that host of little annoyances for doctor and patient, which I may call fuss. Most doctors will agree with me that, save in cases of infants, where the mother cannot and should not be displaced, the best nursing is paid nursing, and the worst very often that which comes from the family."

The *Lancet* says that the New Sydenham Society has purchased the copyright of "Mayne's Medical Dictionary," and will shortly issue a new and greatly improved edition.

British Medical Association.—This body will meet this year in London, on the 6th of August.

The cranial cavity was measured by Morton in 623 instances, the heads being derived from many nations. The largest was that of a German, and measured 114 cubic inches. The smallest, that of an Australian, measured only 58 cubic inches. The cranial capacity of Daniel Webster amounted to 122 inches, and ranks among the largest ascertained; but Dr. T. G. Richardson, in his work on Anatomy, gives the measurement of the head of a German baker in the cabinet of the University of Louisville, the capacity of which was 125.77 cubic inches, thus exceeding by more than three inches the heads of Cuvier and Webster in size. It would be easy to multiply similar instances going to show how uncertain is the size of the head as an index of intellectual power.

A Madame Brès lately passed her first examination for the Doctorate of Medicine in Paris, and the Secretary of the Faculty appended the following particulars to her certificate: "Madame Brès, married, and the mother of two children, has not taken to the study of medicine as a pastime, nor from scientific vanity. She practises all the duties of the profession. During the two sieges which Paris has so lately borne, she never quitted the bedside of the wounded. The rain of honorary distinctions poured upon the ambulances passed by without falling upon her; the devotion natural to woman needing neither stimulus nor flattery."

We note the severe wounding of Acting Assistant-Surgeon Seimig (?) in the late massacre by the Modocs.

Weekly Return of Deaths and Interments in Philadelphia for the Week ending Saturday, May 3, 1873.

Barometer corrected for temperature, elevation above sea, and instrumental error.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 29, 1873, TO MAY 5, 1873, INCLUSIVE.

Smith, A. K., Surgeon.—When relieved by Assistant-Surgeon Lippincott, to comply with orders from War Department. S. O. 86, c. s., Department of the South.

Peters, De Witt C., Surgeon.—Granted leave of absence for thirty days. S. O. 65, Department of the Gulf, April 26, 1873.

Gray, C. C., Surgeon.—When relieved by Assistant-Surgeon Matthews, to comply with orders received from War Department. S. O. 80, Department of the East, April 29, 1873.

Fryer, B. E., Surgeon.—When relieved by Assistant-Surgeon Moffatt, to comply with orders from War Department. S. O. 65, Department of the Missouri, April 30, 1873.

Weeds, J. F., Surgeon.—When relieved by Assistant-Surgeon Caldwell, to comply with orders from War Department. S. O. 86, c. s., Department of the South.

Happersett, J. C. G., Assistant-Surgeon.—Relieved from duty at Fort Garland, C. T., and assigned to duty at Fort Lyon, C. T. S. O. 63, Department of the Missouri, April 26, 1873.

Woodhull, Alfred A., Assistant-Surgeon.—Relieved from duty at Fort Lyon, C.T., and to comply with S. O. 82, c. s., War Department. S. O. 63, c. s., Department of the Missouri.

Brewer, J. W., Assistant-Surgeon.—Relieved from duty at Camp Supply, I.T., and to comply with S. O. 82, c. s., War Department. S. O. 63, c. s., Department of the Missouri.

Gardner, W. H., Assistant-Surgeon.—Relieved from duty at Fort Hays, and assigned to duty at Camp Supply, I.T. S. O. 63, c. s.. Department of the Missouri.

Caldwell, D. G., Assistant-Surgeon.—Assigned to duty at Nashville, Tennessee. S. O. 86, Department of the South, May 2, 1873.

Lippincott, H., Assistant-Surgeon.—Assigned to duty at McPherson Barracks, Atlanta, Georgia. S. O. 86, c. s., Department of the South.

Meacham, Frank, Assistant-Surgeon.—Relieved from duty in Department of the Platte, to proceed to Boston, Massachusetts, and on arrival there report by letter to the Surgeon-General. S. O. 87, A. G. O., April 26, 1873.

Moffatt, P., Assistant-Surgeon.—Assigned to temporary duty at Fort Union, N. M. S. O. 65, c. s., Department of the Missouri.

King, J. H. T., Assistant-Surgeon.—Relieved from duty in Department of the Platte, and to report in person to the Commanding General Department of the Lakes, for assignment. S. O. 87, c. s., A. G. O.

Matthews, W. Assistant-Surgeon.—Assigned to temporary duty as Post Surgeon at Fort Wood, New York Harbor. S. O. 80, c. s., Department of the East.

Mackin, Jr., Chas., Assistant-Surgeon.—His resignation accepted by the President, to take effect April 29, 1873. S. O. 89, War Department, April 30, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON PELVIC NECROSIS.

BY H. ALLEN, M.D.,
Surgeon to the Philadelphia Hospital.

GENTLEMEN: I propose to-day to speak of some of the conditions arising from disease of the bones of the pelvis. As you are aware, the pelvis is protected at its sides by the gluteal masses of muscles, whose outlines are continuous with those of the adductor and flexor muscles of the thighs. This arrangement essentially excludes examination of the sides and inferior margins of the pelvis during life, while the state of the interior can be only approximately estimated by the inspection of the outlet of the pelvic organs. Occasionally much light can be gained by the last-named procedure: this failing, we are in the dark. Let us suppose that a case of chronic disease of the pelvic bones, attended with suppuration and the formation of fistulæ, is presented. We are able, we will suppose, to eliminate all diseases of the pelvic viscera, may exclude coxalgia, and yet we may be uncertain as to the exact nature of the trouble. Of the two examples which will be narrated to-day, you will perceive that the observer might well be excused for hesitating in forming positive opinions about the conditions actually existing, and for leaning to conservative methods of treatment.

Case I.—H. McC., male, colored, aged 33, laborer, was admitted to the Philadelphia Hospital, November 17, 1870, with what was believed to be venereal disease. He was received into the Men's Venereal Ward. The right groin was the seat of sinuses; the testicles were swollen. No history of his condition prior to admission was at all satisfactory. He came under the notice of the writer October, 1871. His state at this time was as follows: He was bedridden and much emaciated; the right groin presented the appearance of chronic virulent bubo; the glands were enlarged and painful, and undermined here and there with pus, which had found vent through several fistulous orifices. One of these tracts permitted the introduction of a curved probe downwards and inwards beneath the great vessels. Several cicatrices, the results of opening old sinuses, marked the region. The right half of the scrotum exhibited an opening of a purulent tract. This was situated a little to the left of the femoro-scrotal fold; both testicles were somewhat enlarged; no fistulæ were found in the left groin; the lymphatic glands were not enlarged. When the patient was directed to lie upon his face, an indurated patch of tissue was traceable from the flexor aspect of the thigh at its lower third to the ischio-rectal fossa; a probe passed along the sinus, corresponding to the tract, met with no resistance. The decubitus was upon the right side, with the legs flexed. The discharge was fetid and profuse, necessitating frequent renewals of the dressings. The man was listless, appeared to suffer no pain, slept fairly, and had a moderate appetite. He was fond of lying with his head enveloped in the covering of the bed.

It was deemed advisable to preserve perfect rest of the sinuses; and to this end the limb was extended, and a straight splint was applied to the outer side. The discharge, however, continued as profuse as ever, and after a trial of several weeks this was abandoned. It was now strongly suspected that the trouble was not of venereal origin; and in November a careful examination of the sinuses was made, the patient being under the influence of ether. It resulted in finding within the large posterior sinus a piece of bone, about the size and shape of half a chestnut. This discovery threw a flood of light upon the case, and the patient was thereupon transferred to the surgical ward. The limb was kept at rest in the extended position, and after a rest of a week the sinuses were again explored, and several small fragments removed. It was noticeable, however, that, notwithstanding the withdrawal of these offending masses, the amount of the discharge did not materially lessen. February 21, a third examination was made, with a view of determining whether some portions of bone might not be lodged deep within the parts, and so situated as to have escaped previous examination. This was, indeed, the case, for lying apparently within the thyroid foramen were felt a number of roughened fragments, which had not, therefore, entered the sinuses, although doubtless instrumental in maintaining them. The fragments were removed. But it soon became evident that the condition of the patient had not been dependent, in the late stage of the disease in which he had come under observation, upon a merely local cause. He complained of wandering abdominal pains. Hectic set in, with its accompanying symptoms; he gradually sank, and died May 25. At the post-mortem examination, it was found that the innominate bones were disjointed at the symphysis pubis, and the soft parts destroyed. The abdomen was the seat of chronic peritonitis; the folds of the small intestines were agglutinated; six ounces of pus was found in the peritoneal cavity; the muscles about the pelvis were consolidated by inflammation; the bones when macerated exhibited loss of tissue along the left pubic bone and ischium to the posterior and median borders; the right pubic bone was much excavated upon the anterior surface; conspicuous osteophytes were seen upon the ascending ramus of the ischium, as well as along the horizontal rami of both pubic bones; the other organs revealed no organic change; no evidences of syphilis were detected.

It will be seen that the above case resembled, in some particulars, a case of virulent bubo. The sinuses in the groin, associated with engorged lymphatic glands, recalled a condition which, as you know, is a common one in our wards. The quantity of matter which daily escaped was much greater than is seen in an ordinary peri-adenitic bubo; nor was the pus of the same quality. We have not seen in this clinic, among the numerous examples of pus-yielding inguinal fistulæ which we have studied together, any instance of fetid pus. Here, however, and, as a rule, in all examples of pus dependent upon disease of bone, fetor is a prominent characteristic. With respect to the position of the sinuses, we do not expect inguinal fistulæ which are due to glandular irritation to be associated with sinuses upon the back of the thigh and the perineum. The presence of symmetrically-enlarged testicles suggested syphilitic infection. But upon this point there was no evidence, and the presence of pus on the right side of the scrotum would account for the secondary engorgement of the testicle of that side.

It is apparent, moreover, that the diagnosis of venereal disease would have been untenable after thorough exploration of the sinuses. Fistulæ, following necrosis of the pelvic bones, when situated in the perineum, have been mistaken for fistulæ in ano, and the grave error has been committed of operating as for that disease.

The case before us is illustrative of the great local change which may follow upon exfoliation of the pubic and ischiatic bones. The ascending ramus of the ischium and the descending ramus of the pubic bone were involved, and the exfoliations had been separated both from the anterior and the posterior surfaces. In the great majority of cases of pelvic exfoliation, it is found that the parts which are most intimately connected with the adductor and flexor muscles of the limb are those which suffer. This localization is not without interest. The origin of many cases of pelvic necrosis can be traced directly to unusual tension of these powerful muscles, as in the acts of running, dragging nets, lifting heavy weights, etc., and the moment of reception of the injury and its exact locality be accurately determined by a sharp twinge of pain. In the absence of an account of such pain, the fact of indirect injury must remain unproved. Another important point to remember in the history of the case is the abscess which commonly ushers in non-specific necrosis. In our own case it has been seen that no history worth considering was elicited, and we were entirely dependent upon the fortuitous detection of an exfoliated portion of bone.

Case II.—A. W., female, aged 44, widow, admitted to the Philadelphia Hospital January 1, 1873. For three months she had complained of pain in the right iliac region. This was never severe, though subject to exacerbations. About a month prior to her admission a minute pustule formed in the iliac region, about the inner third of the ilio-pubic space, and half an inch above Poupart's ligament, which, discharging its contents, was converted into a fistula. At times an ill-defined swelling would occupy the entire iliac region, and become sensitive to pressure. At intervals of about two weeks, and with tolerable regularity, this collection would discharge itself, giving great relief to the patient, and followed by subsidence of the iliac tumor, with apparent improvement in the general condition. After one of these periodical evacuations the patient's appetite would increase, her manner become more animated, and she would pass from a condition of depression and melancholy to one of comparative content and hopefulness. The vomiting which almost invariably preceded these discharges would stop at the same time, and on several occasions diarrhœa, which had persisted obstinately for several days, and had even threatened the patient's life, would also stop spontaneously. According to the accounts of the nurses and of the woman herself, the amount of pus discharged at these times varied from half a pint to a pint. With the exception of these occasional periods of relief, there was a steady deterioration of the general condition, with marked anæmia and emaciation. The case was first looked upon as one of iliac abscess, dependent upon a transmitted irritation from the cœcum. This, as is well known, is an occasional sequence of typhlitis. The previous history was so obscure that the probability of suppuration existing beneath the peritoneum upon the bed of the internal iliac muscle was continually presenting itself to us. This opinion we were compelled to modify when the periodical discharges became so noticeable a feature. The quantity of pus was altogether disproportionate to the alleged cause. It was now thought that the case might be one of necrosis of the pelvic bones, and possibly one in which a fragment of bone was lying within the pelvis and exciting the formation of pus. The patient was placed under the influence of ether, and the opening explored. The probe could be passed upward along the tract for the distance of about two inches, and downward towards Poupart's ligament. No dead bone was anywhere detected, and the nature of the case remained as doubtful as before. Fearful of complication with the cœcum, we did not feel authorized to open the tract. In our opinion, no good could possibly have followed an incision through the parietes, when there was no surety of the condition of parts beyond. The patient died April 12, 1873. At the autopsy, which was made thirty-six hours after death, the abdomen was opened by the usual crucial incision. The intestine was found to be free from adhesions, excepting the last four inches of the ileum, which were fixed by old bands of lymph to the wall of the true pelvis. The cœcum and sigmoid flexure were normal. About an ounce of healthy pus was found in the cavity of the pelvis. There was nowhere any evidence of peritonitis. The opening in the wall of the abdomen was made at the position of the fistulous orifice. A probe could be passed downward along the tract to just above Poupart's ligament, whence it passed beneath the peritoneum along the brim of the true pelvis to communicate with a large cavity lying upon the venter of the ilium. The tissues were greatly infiltrated, and the periosteum destroyed. The bone was found discolored and much roughened. No exfoliations were found. The collection had passed down within the true pelvis for a short distance, but here was not in contact with bone. The sacrum was, however, denuded at the central portion of its middle third. No pus was found along this tract; it had doubtless been recently evacuated through the opening in the abdominal walls. A second collection, however, to the left of the sacrum, was seen in position. This extended along the sheath of the psoas muscle, and contained about eight ounces of pus. It had not apparently communicated with the larger tract, nor was it at any point in contact with bone. The pelvic organs were healthy. No lesions found in other viscera.*

In both of the above cases disease of bone can with propriety be assigned as a cause of the obscure and complicated lesions. In the first, multiple fistulæ associated with exfoliation of bone from the region of the pubic and ischiatic bones; in the second, a single fistula due to deep-seated suppuration about a necrosed surface of the innominate bone, and secondarily, we may surmise, the anterior surface of the sacrum. In both the direct causes were obscure: over-excitation of the parts involved, by powerful muscles operating within a small area, explains, it is thought, the first, but not the second, where muscular traction is not known to induce such results. The chief interest attending the disease is the difficulty of making a diagnosis; for the *treatment* of pelvic necrosis is in no wise different from that of the same disease in other portions of the skeleton. Occasionally when fragments of bone are deeply placed *within* the pelvis, great discretion must be exercised in removing them. If perito-

* The writer is indebted to Drs. J. W. White and J. B. Walker for the notes of this case.

neal irritation be already excited, as was found in Case I., it is unnecessary to dwell upon the dangers arising from an exploratory operation to remove fragments which lie within the foci of greatest danger to the serous lining of the abdomen. In order to remove hidden portions of exfoliated bone which do not lie in positions accessible to instruments inserted along the sinuses, the surgeon may be compelled to make an incision remotely placed to the orifice of the fistula. In a case recorded by Syme in his "Clinical Observations," he was obliged to divide the integuments for the distance of three inches along, and a little above, the crest of the ilium, to extract an exfoliation which was found lying in the iliac fossa. In Case II. it is evident that little if anything could have been accomplished by such an incision, and we believe our patient's life was prolonged by the conservative policy we pursued.

ORIGINAL COMMUNICATIONS.

REPORT OF A CASE OF COMPOUND COMMINUTED FRACTURE OF THE SKULL WITH EXTENSIVE LOSS OF BONY TISSUE, WITH RECOVERY; AND OF A CASE OF AMPUTATION OF BOTH LEGS FOR FROST-BITE, DEATH OCCURRING ON THE TWENTY-FIRST DAY.

BY J. FRAZER BOUGHTER, M.D., U.S.A.,

Fort A. Lincoln, Dakota Territory.

PRIVATE JOHN O'H., Sixth U. S. Infantry, æt. 37, while engaged in cutting logs in the timber near the post, on the 26th of September, 1872, was struck on the left side of the head and on the left forearm by a large cottonwood-tree falling upon him.

The accident occurred about 9 A.M.; he was brought to the post and admitted to the hospital (field*) at 12 M.

The patient was suffering from concussion of the brain, and was in a state of profound insensibility.

Examination revealed a very extensive compound comminuted fracture of the left parietal bone, and a simple fracture of the left forearm (both bones) at the upper third, that of the ulna being very oblique. One large fragment of bone (nearly two square inches of surface) was almost entirely detached, held only by its attachment to the temporal muscle. At first sight the contused and lacerated muscle was supposed to be oozing brain-substance, discolored by dirt and blood. Washing the parts disclosed its true nature.

This fragment had been entirely detached from the dura mater, apparently without injuring it in the least, —*peeled* off, so to speak.

In addition, several smaller fragments of bone were removed.

Three lines of fracture, each several inches in length, radiated off from the triangular space left vacant by the removal of this fragment of bone,—one anteriorly towards the coronal, the second superiorly towards the sagittal, and the third posteriorly towards the lambdoidal suture.

The scalp was lacerated and torn in various directions.

Having ascertained that no depression of bone existed, the dirt and blood were carefully washed away, the rough and projecting edges of bone removed, the scalp shaved, the lacerated edges brought together by sutures and ichthyocolla plaster; the large portion of the temporal muscle, which at first it would have seemed better to remove, was laid over in its place and covered with portion of the scalp.

The fracture of the forearm was dressed with splints.

Carbolic acid solution (℞ Acid. carbolic., ʒij; aquæ, ℥xij. M.) used to constantly saturate the lint laid over the wound; cold applications directed to be kept constantly applied to the head (no ice being attainable, cold spring-water used).

Unable to swallow any fluids.

September 27.—Still suffering from concussion; no change in the wound; able to swallow a little beef-essence and milk.

September 28.—No change; still insensible; continues to take beef-essence and milk.

September 29.—Patient has spoken for the first time since his injury; treatment continued.

September 30.—Still about the same; ordered ℞ Olei ricini ℥j at 9 A.M.

October 1.—Bowels moved yesterday P.M.; consciousness slowly returning; he is rational at times, and responds when spoken to; ordered milk-punch; tea and bread allowed; treatment continued.

October 2.—Although seven days have elapsed since the patient was injured, there is an entire absence of any symptom of inflammation of the brain or its membranes. The parts are in a remarkably healthy condition.

To-day a demonstration was made against the post by the Sioux Indians, and very brisk firing maintained for some time. The dead and wounded scouts (Indians) were brought into the hospital, and, notwithstanding all the unavoidable excitement at such a time, the patient, who knew what was occurring, did not suffer from any excitement, which was very much feared.

October 3–4.—Takes nourishment well. The scalp becoming swollen and œdematous over the line of fracture extending towards the sagittal suture, an incision was made several inches in length, with a free escape of healthy pus, one vessel divided requiring ligation; parts brought together with adhesive plaster, sutures making too much tension.

October 5.—Doing well this morning; speaks distinctly; a number of purpuric spots have appeared over the body.

October 6.—Improving; purpuric spots increasing.

October 7.—Applied compress and bandage to head; readjusted splints to forearm; it is extremely difficult to keep them applied, as the patient is very restless. Treatment continued.

October 8–14.—Improving; bowels now act daily; milk-punch stopped the 14th inst. Full diet allowed.

October 15–19.—Improving; parts are healing rapidly; has no pain whatever; stopped beef-essence the 19th instant.

October 20–26.—Still improving; the splints were removed this A.M. (26th inst.); the bones of the forearm show no tendency whatever to union; readjusted.

October 27–31.—Patient still gaining; treatment steadily continued.

November 1.—Moved from the tent into a room in the hospital building (still unfinished).

November 2.—Wounds of scalp healing rapidly. The carbolic acid lotion was changed to the carbolated ointment of the oxide of zinc, and earth-dressing applied to several granulations (the earth has a marked and rapid influence in removing unhealthy and profuse granulations).

November 3.—The earth-dressing has lessened the size of the granulations. Patient allowed to sit up for the first time.

November 4.—Removed splints again; the radius has

* By this are meant hospital tents.

united with some little deformity; no union of the ends of the ulna has taken place, nor is there any evidence of the deposition of callus.

November 5.—Ordered ℞ Tinct. ferri chloridi, gtt. x, three times daily.

November 6–16.—Improving rapidly; sits up every day. Removed a very small fragment of exfoliated bone from the wound of scalp this A.M. (16th instant).

November 17–22.—Allowed exercise in the open air to-day (22d instant).

December 2.—Removed a very small fragment of exfoliated bone.

December 26.—Removed and stopped all dressings to head, finding it entirely healed; the scalp has united and cicatrized over the large space left vacant by the loss of bone in a very perfect manner, adhesions having formed with the exposed portion of the dura mater.

February 20.—Removed splints from the forearm; no union of ulna; frictions, rubbing the ends of the fragments together, and everything save an operation, has been tried, but without any success. As the radius has united, as flexion and extension are perfect, and supination and pronation almost so, and, further, as the man has a very good and serviceable arm (though with some deformity), it is not deemed advisable, in consequence of the injury to his head, to attempt an operation for ununited fracture, which might not be a success.

This man has been recommended for a discharge from the U. S. service.

AMPUTATION OF BOTH LEGS FOR FROST-BITE, DEATH OCCURRING ON THE TWENTY-FIRST DAY.

Charles P., æt. 21, a citizen, engaged in wood-chopping above the post, was admitted to the post-hospital, with both his feet badly frozen, on the 23d of March, 1873.

On the afternoon of the 22d instant, with a companion, he started on a hastily constructed raft from his log cabin, which had been surrounded by water by the overflow of the Missouri and Heart Rivers. Towards evening the temperature *fell rapidly*. They pushed their way through the ice till 8 P.M., when they abandoned the raft, and started on hands and knees, crawling over the thin ice; the patient broke through, his clothing becoming thoroughly wetted; he lay all night on the ice, his feet *freezing solid* (in the morning the thermometer at the post recorded 0° (zero) Fahrenheit); the ice being firm enough to enable them to reach the shore, they walked to the post, a distance of four miles, arriving here at 6.30 A.M.

Saw patient at 7.30 A.M., March 23; found him much exhausted, *with his boots on*, and his feet in a tub of cold water, in a room in a log cabin without fire; had boots carefully cut off; found the right foot frozen stiff and solid to the ankle-joint; the left as far as the lower third of leg, the ankle-joint of this leg being immovable, the foot being somewhat everted, resembling talipes valgus.

Ordered his feet to be constantly rubbed with snow and ice-water; no fire to be made; dry clothes put on; whisky and some food administered.

After friction had been continued as above for eight hours, the parts became soft and natural, *but no warmth returned*. The ankle-joint of the left foot now permitted of some movement.

Patient now (4 P.M.) admitted to hospital. Dry frictions with red flannel continued for some time; the frozen parts painted with tinct. iodin. comp., and both feet and legs enveloped as high as the knee in cotton batting. Tea, toast, and milk allowed.

℞ Morph. sulph., gr. ¼, give at 8 P.M., and repeat in two hours if necessary.

March 24.—Slept some last night; has no pain; sensation in the feet not entirely destroyed.

10 A.M., pulse 72, temperature 99°; 8.30 P.M., pulse 90, temperature 100°. Tinct. iodin. comp. continued.

March 25.—10 A.M., pulse 80; temperature 100°. 8.30 P.M., pulse 88; temperature 100.5°.

March 26.—10 A.M., pulse 84; temperature 100.5°. 8.30 P.M., pulse 86; temperature 100.5°.

March 27.—10 A.M., pulse 78; temperature 99.5°. 8.30 P.M., pulse 92; temperature 101.5°.

March 28.—10 A.M., pulse 74; temperature 99.5°. 8.30 P.M., pulse 76; temperature 100°.

March 29.—10 A.M., pulse 94, temperature 104.5°. 8.30 P.M., pulse 125; temperature 106°.

The patient is very restless; has a very high fever; had a severe chill during the morning, and vomiting. Beef-essence ordered to be taken freely.

March 30 (The clinical thermometer was accidentally broken after taking the temperature last evening).—The feet still remain cold, becoming discolored. Can feel pinching of the toes very slightly. A faint line of demarcation is declaring itself.

10 A.M., pulse 88. 8.30 P.M., pulse 100.

March 31.—Had a very severe chill at 10 A.M. Ordered ℞ Quiniæ sulph., gr. v, spirit. frumenti, ℥j. M., at once.

11 A.M., pulse 112. Ordered ℞ Tinct. ferri chloridi, ℥ij, quiniæ sulph., gr. xxiv, aquæ, ℥xij. M. Sig., a tablespoonful three times daily, before meals. Sherry wine, ℥ij, three times daily. Continue beef-essence, milk, and toast.

The line of demarcation is becoming more evident; it is feared he will lose both his feet. 8.30 P.M., pulse 104.

April 1.—Evidence of the invasion of gangrene; the feet are becoming shrivelled and dry; a bad odor is perceptible this morning during the dressing.

10 A.M., pulse 103. 8.30 P.M., pulse 90.

March 2.—The line of demarcation is now almost established for the right foot, the parts below becoming very dark.

10 A.M., pulse 98 (very weak). Milk-punch substituted for the sherry wine, to be taken every hour. Says he cannot take the beef-essence any more, as it makes him sick.

The "earth-dressing" was applied to both feet this morning (for its deodorizing property).

8 P.M., pulse 100. Says the dressing of this morning feels better than anything he has had applied yet. *Not the slightest odor perceptible this evening.*

April 3.—Earth-dressing renewed this morning; slept well last night, and had much less pain than usual in his feet. Pulse, 8 A.M., 96. 8 P.M., 80.

April 4.—Doing well. Slept well, after taking morph. sulph., gr. ¾, last night. 10 A.M., pulse 104.

Renewed dressing at 6 P. M. Complains of sick stomach. 8.30 P.M., pulse 104; temperature 102.5° (obtained a clinical thermometer this afternoon). Ordered morph. sulph., gr. ¼, every hour till he sleeps.

April 5.—10 A.M., pulse 114; temperature 103°. Amputated right leg at lower third, and as far down as healthy tissue could be found, by the circular method. Ether used at first, but, as it did not produce complete nor rapid anæsthesia, chloroform was substituted. Lost but little blood during operation; tourniquet applied to the popliteal artery; four vessels ligated. At 2 P.M. patient removed to his bed. Pulse 120; temperature 102.5°. As the inflammatory condition of the left leg did not admit, and moreover the danger of the shock in his present condition, it was necessary to defer amputating it, although it had been intended to make a synchronous amputation.

Carbolic acid lotion applied to stump. After operation, gave morph. sulph., gr. ½ (2 P.M.); repeated at 6 P.M. and 8 P.M., the man not having slept any.

8 P.M., pulse 132; temperature 104°. Patient is very weak.

April 6.—All the morphia the patient had administered to him last evening failed to produce any sleep.

10 A.M., pulse 120; temperature 102°.

For breakfast this morning, had two eggs. Ordered ℞ Hydrate chloral, gr. xv, at 10.30 A.M., and repeat in one hour, if necessary.

8 P.M.—The chloral produced no sleep. Bowels moved to-day. Pulse 116; temperature 103°. Ordered morph. sulph., gr ½, at 9 P.M., and repeat if necessary. Continue beef-essence, chicken broth, milk-punch, and milk.

April 7.—Slept a little last night. Doing well this morning. 10 A.M., pulse 108; temperature 99.5°. The stump looking swollen, loosened most of the adhesive straps to permit of free drainage.

9 P.M., pulse 120; temperature 104.5°. Very restless; face flushed; complains of pain in left thigh and groin.

April 8.—No sleep last night, notwithstanding he had taken large doses of chloral. Pulse at 10 A.M. 104; temperature 99.5°. Stump looking well; had it dressed as well as the left leg, and patient moved into a clean bed. The line of demarcation well defined in the left leg; earth-dressing still continued.

9 P.M.—Since 6 P.M. has been very restless. Pulse 136; temperature 105.2°. Complains of severe pain in both legs. ℞ Olei ricini, ℥j, at 9 P.M.; morph. sulph. during night.

April 9.—Last night the patient had gr. 1¾ of morphia, producing but little sleep. Oil operated. Very weak and exhausted. Pulse 140; temperature 104.5°.

9 P.M.—Complains of severe muscular spasm in both legs. Pulse 134; temperature 101.5°; respirations 20.

April 10.—Did not rest any last night, although he had gr. ijss of morphia. The edges of the skin of right stump are sloughing. Pulse 136; temperature 101.5°. Taking beef-essence and milk-punch every hour.

9 P.M., pulse 140, temperature 102.5°. Vomited during the evening. Pulv. opii, gr. ij, ordered, as the morphia has failed to produce sleep. Brandy and water substituted for the milk-punch, as the latter disagrees.

April 11.—Very weak this morning. Pulse 140; temperature 102.5°. Severe vomiting at 10 A.M. The right stump sloughing extensively; ordered a chlorinated poultice to stump. The left leg much swollen above the line of demarcation.

As the patient is becoming weaker, and as every effort to strengthen him has had no effect, notwithstanding his very unfavorable condition, it was decided to amputate the left leg, though with many misgivings as to the result. Accordingly, at 3 P.M. chloroform was administered and the amputation performed at the junction of middle and upper third, by the flap method. Very little hemorrhage. Six vessels ligated; tourniquet applied to the popliteal artery. Came out of the operation well, but very weak; gave ℞ Quiniæ sulph., gr. x, morph. sulph., gr. ½, spirit. vini gallici, ℥j. M.

9 P.M., pulse 150; temperature 104°. Continue beef-essence and brandy, freely.

April 12.—Slept three hours last night. 10 A.M., pulse 126; temperature 98.2°. Right stump improving; continue poultice. Left stump looking well; continue carbolic acid lotion and ice-water, freely. 9 P.M., pulse 144; temperature 100°. Very weak; has been perspiring profusely since 3 P.M.; his hands are very cold. To take brandy and beef-essence (if possible) every fifteen minutes, and ℞ Ammoniæ carb., gr. v, every two hours.

April 13.—Slept but little; constant low muttering delirium during night. Stumps looking well; poultice continued to right, and the carbolic acid lotion to left. As the bed was much soiled, it was changed this morning. 9.30 A.M., pulse 144; temperature 101.5°.

9 P.M.—Patient to-day has been very low. Temperature 102.5°; pulse 144–150. Delirium constant.

Patient died at 12.15 A.M.; at 12 o'clock had taken beef-essence and brandy.

The terrible exposure and suffering this man experienced on the night of the 22d of March was enough, almost, to cause death; and indeed it is a wonder he did not perish outright.

His condition on the 11th of April, when the left leg was amputated (pulse 150, temperature 104°), was most unfavorable for an operation; although the line of demarcation was well declared on the 8th of April, the operation was deferred till the 11th, being kept on beef-essence, milk, and brandy, in hopes that his strength would increase. Death was the result of exhaustion and passive congestion of the lungs.

The value of the earth-dressing was markedly shown in this case.

Examination of both stumps after death showed them to be in an unhealthy condition.

TWO CASES OF GANGRENOUS ERYSIPELAS OF THE GENITALS.

BY ISAAC OTT, M.D.

THESE cases were observed in the practice of Dr. C. C. Field. The notes in the major part were furnished by Dr. Sine.

Case I.—Mr. H., Bavarian, æt. 66; nervo-sanguine temperament; muddy skin; emaciated; farmer; residence in a damp location; father died at 40, of hemorrhoids; mother at 80, of disease not known; his previous health good, except that, during this winter, his appetite was diminished; all viscera normal.

April 13.—Patient perceived, on lower side of prepuce, near the margin, a small red spot, which was attended with slight pain and warmth; at 9 P.M. was seized with chills, lasting a half-hour, alternating with flashes of heat; burning pain in prepuce.

April 15.—Præputial inflammation had extended within an inch of the pubes, here ending abruptly, but extending over anterior surface of scrotum; testes one-third larger than normal, and very sensitive to the touch; dorsal surface of penis covered with a large vesicle; penis swollen and club-shaped; pulse 80; respiration 20.

April 16.—Penis purplish-black; patient very sensitive to cold; tongue more furred; pulse 85; respiration 22.

April 17.—Aggravation of all the previous symptoms.

April 18.—Testes enormously enlarged; scrotum size of a pig's bladder, infiltrated with inflammatory liquids; of sodden appearance, and very sensitive.

April 19.—Penis dying, being of a deep purplish-black appearance; line of demarcation formed within an inch of pubes; scrotum covered with purplish spots; radiating lines of redness over groins; severe chills; typhoid state prominent; pulse 120.

April 20.—Patient restless; complains of much pain; pulse not able to be counted; conscious; inflammation extended above the umbilicus; dark-purple spots over infiltrated abdomen; blood extravasated on posterior surface of trunk; nausea, and constrictive pain about the diaphragm; unconscious for several hours preceding the death at 11½ P. M.

Case II.—Wife of first case, æt. 52; nervous temperament; skin blanched; occupying separate room from husband; parents healthy, so far as known; seven years ago was seized with paralysis on both sides, attended with gradual loss of sight; during the last seven years has been in bed, paralytic and blind; all viscera are normal, excepting the brain.

April 15.—She used her husband's commodes; no copulation has taken place for a long time.

April 16.—There was noticed dark-purple inflammation of vulva; pulse 80; respiration 20.

April 17.—Inflammation extending.

April 18.—Pulse 90; respiration not counted; inflammation has reached the anus and groins; extravasation of blood in depending parts of trunk; complains of much pain; restless; marked typhoid state.

April 19.—Inflammation extending over lower part of abdomen; vulva much enlarged, very dark in color; pulse 130; respiration 26.

April 20.—Pulse 165; respiration 20; sighing inspiration; speechless and senseless; death at 1.45 P. M.

Remarks.—The treatment in these cases was supporting.

What was the origin of this disease? Was it an organic poison from without, absorbed by ruptured blood-vessels of an abraded prepuce, causing septicæmia? Did the organic poison in its proper nidus, with heat and moisture, reproduce other infectious protoplasm, which was absorbed by the vaginal mucous membrane? What are the facts in regard to septicæmia? We believe that Dr. Lancereaux* has proved that in man gangrenous materials can be absorbed by ruptured blood-vessels and cause septicæmia; that Davaine and Vulpian have shown that this human septic blood will produce, in lower animals, especially in rabbits, septicæmia; that it possesses a septicity infinitely greater than that of the organic material itself. All these facts seem to have a bearing on the natural evolution of the disease in the above cases, explain it as we may.

THUDICHUM'S DOUCHE IN A CASE OF FOREIGN BODY IN THE NOSE.

BY FREDERICK P. HENRY, M.D.

THE following simple case will serve to show the good results that may be derived from the use of Thudichum's douche in cases of foreign body in the nasal passages.

A little girl æt. 2 years, in a spirit of mischief or enterprise, had introduced a large-sized shirt-button into her nose. Becoming alarmed at what she had done, she had recourse to her mother, who attempted to remove the button with a crochet-needle.

The maternal efforts not being crowned with success, I was called to their aid. The button was there. I could perceive its edge as it lay septum-like far up in the right nasal fossa. I seized it with a pair of dissecting forceps, but it slipped from their grasp and was propelled still farther up, in the same manner as a wet cherry-stone is shot from the finger and thumb. The nose began to bleed, obscuring the view. The idea of the nasal douche occurring to my mind, I sent a messenger to my office, quite near at hand, for the apparatus.

Placing the vessel containing the water on the dining-table, and a large basin on the floor, I placed the child prone on the nurse's lap, with the face over the basin. The child resisted vigorously, but no sooner was the nose-piece put in position than the button shot into the basin with considerable force, and glanced off to the other side of the room.

The child's cries, which were comprised in one prolonged expiratory effort, seemed to have aided the operation by raising the velum and thereby preventing escape of water into the mouth, which any one who has used the instrument on his own person knows is so liable to occur.

The impaction of foreign bodies in the nasal passages occurs almost exclusively in children, and it might be argued that the douche could not be used on account of the want of co-operation of the patient with the efforts of the surgeon. Such argument is worthless. It is just in these cases that the douche works most effectually, the whole *vis a tergo* being preserved by the complete closure of the posterior nares during the child's cries.

This is a simple measure, and, in all probability, has been often resorted to, but I have seen no mention made of such a mode of treatment for removal of foreign bodies from the nose.

* *Archives Générales*, March, 1873.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

SURGICAL CLINIC OF PROFESSOR S. D. GROSS, M.D., MAY 10, 1873.

Reported by E. E. MONTGOMERY.

GOITRE.

THIS young woman, æt. 19, a resident of this city, comes to us with a tumor of one year's duration upon the right side of the neck. It is of large size, deeply seated beneath the sterno-mastoid muscle, of round shape and inelastic feel; and it moves up and down with the act of deglutition, a fact which shows it to be connected with the thyroid gland.

This disease consists of an enlargement of the thyroid body: either lobe, or the isthmus, may be affected; both lobes are usually the seat of the disease, but seldom in the same degree.

The tumor varies greatly in size, from the slightest enlargement to that of an adult head, reaching from the chin above to the sternum below. It usually increases in size very slowly, but at times may be rapid in its growth, as in the case before us. When of unusual size, it causes difficulty in breathing, headache, vertigo, noises in the ears, and altered voice, owing to the severe pressure to which the vessels and nerves of the neck are subjected.

The internal structure is liable to considerable variety, according to the age and progress of the tumor. When of moderate standing, it is of a soft gelatinous consistence, and emits upon section a ropy, glutinous fluid; later it undergoes a sort of amyloid degeneration, and concretions sometimes appear, either alone or combined with cartilaginous and osseous formations.

In the cystic variety we have one or many cysts forming in the substance of the gland. These cysts sometimes become enormous, holding as much as fifteen to twenty ounces of a serous fluid. This variety is easily recognized by its growth, fluctuation, and its movement with the larynx. If in any case there is doubt in regard to its character, it may be easily determined by means of the exploring-needle.

The causes of this affection are unknown. It is endemic in the valleys of Switzerland, and in other parts of Europe, and exists to some extent in the mountainous

regions of our own country. Drinking of snow water has been assigned as a cause, but it is more probable that it is due to some peculiar condition of the atmosphere.

The diagnosis of this tumor is comparatively easy. Its appearance, progress, and position, together with its movement up and down with the larynx, plainly indicate its character. The only affections with which it is liable to be confounded are, aneurism of the carotid artery, varix of the internal jugular vein, cystic tumors of the neck, and enlarged lymphatic gland.

When the tumor is excessive, a part of it may project over the artery and receive pulsation from it, thus easily leading to the idea of an aneurism; but the signs of distinction are: the absence of whirring sounds, the indolent character of the growth, and the ease with which it may be pushed away from the artery when the muscles are relaxed.

Varix is very rare in this situation, occurs in the lower part of the neck, is of a bluish color, and transmits a soft, tremulous pulsation to the touch.

Cystic tumors are generally small, and move with the trachea; doubtful cases may be determined by means of the exploring-needle.

Enlargement of a lymphatic gland usually occurs in patients of a scrofulous diathesis. The history, hardness, tendency to suppurate, and connection with other enlarged glands, establish the diagnosis.

Treatment.—When there is any heat in the part, my usual course is to apply leeches, and afterwards to use an ointment of the biniodide of mercury, which has been found a powerful sorbefacient: this, however, should not be applied just as it is dispensed in the shops, as it is much too strong. We will take one part of the ointment to eight of simple cerate, and of this will apply a small portion to the surface of the tumor daily, it being carefully washed previously.

Internally, we should expect the best results from some preparation of iodine: therefore we shall give this patient liq. iodin. comp., gtt. x, three times daily, and at the same time admonish her to abstain from meats and live upon plain mild diet.

In the cystic variety, the resolvent treatment is useless; here our only choice is either the trocar and the subsequent injection of iodine, or, with the knife and director, carefully to cut down, layer after layer, and enucleate the cyst. Extirpation of the gland has been practised, but with rather unfavorable results. Dr. Maury, of this city, has twice performed the operation, once with entire success.

When the gland is much enlarged, it must be a bold and fearless surgeon that would undertake such an operation, inasmuch as every step is accompanied with difficulties.

Sanitary Value of Light.—Professor W. A. Hammond, in *The Sanitarian* for May, argues strongly in favor of a freer admission of light to dwellings and school-rooms. After mentioning numerous illustrations of the effect of this agent upon normal and abnormal conditions of the body, he says:

"As has already been intimated, the management of the light in the sick-chamber is rarely the subject of intelligent and scientific action. In anæmia, chlorosis, phthisis, and in general all diseases characterized by deficiency of vital power, light should not be debarred. In convalescence from almost all diseases it acts, unless too intense or too long continued, as a most healthful stimulant, both to the mental and physical systems. The evil effects of keeping such patients in obscurity are frequently very decidedly shown, and cannot be too carefully guarded against by physicians. The delirium and weakness which are by no means seldom met with in convalescents kept in darkness, disappear like magic when the rays of the sun are allowed to enter the chamber. I think I have noticed that wounds heal with greater rapidity when the solar rays are occasionally allowed to reach them, and when they are as far as possible exposed to diffused daylight, than when they are kept continually covered.

"In this country it is rarely the case that disease or injury is induced by excessive light. Occasionally, however, we meet with eye-affections due to excessive light, either coming directly from the sun, or reflected from water, snow, or sand, or resulting from the intense light of a flash of electricity passing near the individual. Bright artificial light may also cause derangement of the visual organs. A child of my acquaintance was rendered permanently amaurotic by looking intently at a bright object while her photograph was being taken.

"The practical application of these imperfect remarks is this, that care should be taken both in health and disease to insure a sufficient amount of light to the inmates of houses, and that it is impossible to rear well-formed, strong, and robust children unless attention is paid to this requirement. Sun-baths, or apartments in which the solar rays can fall upon the naked body, are doubtless highly advantageous to health, and rooms for this purpose could probably easily be constructed in or on most of our city houses. At present a chief object of city families seems to be to devise means for keeping the sunlight out of their houses. That this is contrary to nature needs no argument. The world is said to be under-fed, it is certainly under-lit as we manage it. Let us, then, to use the dying words of Humboldt, have '*Mehr Licht.*'"

Congenital Deformity of the Clavicle (*Irish Hospital Gazette*, February 15).—Dr. Bennett said that the specimen he presented was met with in the dissecting-room, and therefore devoid of history. His attention was drawn to it by observing an enlargement of the outer end of the left clavicle, and he thought at first it was an instance of united fracture of that bone between the conoid and trapezoid ligaments, which usually give rise to bony excrescences. There was no difference in length between the two clavicles. The sternal articulation was normal. The enlargement extended as far as a sharp V-shaped ridge to the outside of the conoid tubercle. The acromial extremity of the clavicle was bifid; one termination was the normal one, and articulated naturally; the second, larger than the preceding, projected backwards outside the conoid tubercle, and articulated by a complete joint with the upper border of the spine of the scapula. This joint was separated by half an inch from the normal articulation, and extended backwards one and a half inch on the spine of the scapula. The conoid ligament was normal, but the trapezoid was greatly enlarged, and extended farther in than natural. There was a distinct articulation between the clavicle and the coracoid process (Knox's joint). In united fractures between the ligaments, bony growths extend downwards through them, so that they may even become anchylosed with the coracoid process; but in this case the ligaments were perfectly free. Dr. Bennett was not aware of any similar case, nor could he explain this excrescence by any morphological analogy. The perfect articulation showed that it was not an exostosis; he therefore regarded it as a congenital malformation. The only objection to this view was its not being symmetrical.

Elongation of the Uvula.—Dr. F. B. A. Lewis, in the *Boston Medical and Surgical Journal* for April 17, records the case of a farmer, æt. 40, in whom the snipping off of one-fourth of an inch of the elongated uvula gave immediate relief to a distressing irritative cough, which had interfered with his sleep and greatly impaired his general condition.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 17, 1873.

EDITORIAL.

"OPIUM-EATING IN MASSACHUSETTS."

IN the London *Lancet* for April 12, there is, under the above heading, an editorial article, upon which we cannot help making a few comments. The writer says, "Some months ago we drew attention to the increasing prevalence of opium-eating on the American continent, and to the fact that the habit was assuming such proportions as to cause considerable uneasiness among the medical profession of the country. Some interesting particulars bearing on the vice may be gathered from the last annual report of the State Board of Health of Massachusetts. The Board sent out the following questions to all the medical men practising in the State: 'Are preparations of opium used by the people except for the relief of pain? Has the injurious use of opium increased of late years?—and, if so, what is the cause of such increase?' One hundred and twenty-five gentlemen replied to these questions, in terms which may be summed up as follows: Forty reported that they did not know of any cases of opium-eating, or that it was used for other than medicinal purposes; while the remaining eighty-five stated that the habit prevailed considerably in their various districts and localities, and was increasing in extent."

The usual fearful array of enormous doses of various opiates is then given; but the author thinks these representations must be received with caution, since "It must be remembered that in the States the drug probably contains many matters besides the inspissated juice of the Papaver somniferum; while the possibility of the 'vamping' brush having been called into requisition in collating the reports must not be lost sight of."

He next quotes some of the assigned causes which led to the practice of habitual opium-eating, and winds up by saying, "It is difficult to devise a remedy for what threatens to become a corroding ulcer in the national life of the great Republic. It must, however, in view of the 'smartness' which would quickly evade legal restrictions or duties on the sale of the drug, be a moral and an educational one."

It may have been ignorance on our part, but we really were unaware that the opium habit was increasing in this country to such an extent "as to cause considerable uneasiness among the medical profession;" and the Massachusetts State Board of Health would seem to have been less impressed by their own statistical results than the *Lancet* was; since in their last report, published in January of this year, they make no allusion whatever to the subject.

We do not know why "in the States" the supply of opium should be any more likely to be adulterated with "many matters" than elsewhere, or why our reports should be suspected of being "vamped" to a greater degree than those of other countries.

The *Lancet* is worried about opium-eating in the United States; but the drug used is probably weakened by adulteration, and the reports are exaggerated; still, the nation's life is threatened, but the people are so incorrigibly evasive of law that the remedy must be "moral and educational." Altogether, the mind of this sympathizing writer seems to have been somewhat befogged.

Much in the same way, in private life, have we heard a piece of scandal produced and commented on among a parcel of old ladies,—holy horror, semi-incredulity, pious good wishes, and cheapening of chances for reform,—the whole thing. It is as neat a "bit" of human nature as one often meets with.

REVIEWING.

ONE of our British cotemporaries has recently expressed itself on the subject of the reviewing of medical books, and, by way of showing how the thing ought to be done, has proceeded to give a sort of clinic, the surgical works of Messrs. Erichsen and Bryant and of Prof. Gross filling the *rôle* of patients. Assuredly the lecturer wields a skilful pen, and demonstrates the operation effectively; but he has set us to thinking.

Reviews, like books, vary much in their style, their object, their elegance, and their truth. There are writers of reviews who think an author is fair game, to be hunted down; there are others who think him a peg upon which to hang an exhibit of their own wit and learning. Some can see only merits, or only faults; some are so influenced by the author's style that they are equally blind to his reasoning or to his want of it. Some are so far forgetful of the responsibility of their task that they allow personal feelings, friendship, animosity, or jealousy, to give tone to their criticisms.

All this is wrong. The object of the reviewer should be to give his readers a calm and dispassionate estimate of the book submitted to him, with such an idea of its general scope and drift as may enable them to judge of its bearing upon whatever branch of science it may treat. Whatever merits, and whatever defects, it may possess, should be pointed out, with neither fear nor favor. In no other way can such a verdict be given as will be sustained by the general voice. Criticism can neither make nor break the fortunes of a literary or scientific work, although it may influence them with a limited number of readers, who prefer having their minds made up for them by others. We venture to assert that no book has ever been unjustly dealt with by the profession at large; and this is the real tribunal by which it is to be judged.

LEADING ARTICLES.

LIFE-INSURANCE.

THE article upon "A Life-Insurance Case," in the number of this journal for May 3, opens a subject of great interest to the profession, as well as to the assured. We who have had experience in the business have seen much of the undue eagerness of agents to force unsafe risks upon the companies in order to secure their commissions; and I believe by some offices such a curious view is held, that the examining doctors, when unsalaried, are only paid for those that they pass. Could there be a greater inducement for carelessness than such an arrangement as this?

Applicants also are frequently, through ignorance, and through instructions from solicitors, led into wrong. Only to-day, a gentleman applying for insurance told me that before he had seen the physician he casually fell into a conversation with the agent about himself, and mentioned some symptoms which may have been of great or of little importance, but certainly demanding serious attention. "Oh," said the agent, "you needn't say anything to the doctor about that." And, thus instructed, and thinking it all right, I believe he acted. In view of such facts as these,—and they are by no means of unfrequent occurrence,—how careful should the companies be in the selection of those officers whose business it is to protect both the assurers and the assured! The medical officers should be entirely independent; any attempt to influence them should be regarded as officious interference, and the agent should be punished by dismissal.

These views are founded upon others, which I hold in common with many, and which, I think, ought to govern the ruling principle in legal cases.

We all know of the long list of questions which are sent to physicians to answer after the death of one whose estate holds a policy upon his life. These questions are of more or less weight, but some of them indicate a disposition on the part of the companies to get rid, if possible, of their obligations. I have now in my possession a letter from a high officer in a company of great pretensions, asking me in reference to a man over forty years of age, and who had died of smallpox, whether he had been successfully vaccinated. I do not know whether the officer was interested in vaccination statistics or not, but it looked to me very much like an attempt at quibbling, not at all compatible with the dignity of a great company, that puts enormous figures upon its sign-boards and advertisements.

I hold that there are but two subjects of inquiry before the payment of a loss,—the *identity* and the *death*. Was this A. B. mentioned in this policy? Were you present at A. B.'s death, or have you seen his body since? If not, please refer us to some one who has seen it.

I cannot think of anything in human pursuits that is analogous to life-insurance. It is not, as is sometimes said, just like any other business. It is the only business that is founded upon absolute certainty, and that is the death of *all* the assured. In making up the tables, therefore, upon which its premiums are founded, nothing that contributes to the death-rate of a community, including margins for epidemics, has been left out. Suicide, murder, accident, rows, mania â potu, syphilis, and all the numerous and varied ills that come from man's imprudence and frailty, are included. Why, then, *having once accepted a risk*, should the assurer claim exemption from payment if the death occurs from one of the causes indicated? Has he a right to exclude what he fully included in the basis upon which he made up his risk?

"Having once accepted a risk" I italicize, and

there is the important point. The common, and universally admitted, use of the word risk in conversation and writings upon the subject of life-insurance, indicates what it really is. The death is certain; the risk is as to how and when that death will occur. Now, as human frailty is in a very great measure a producer of death, it becomes to the companies one of the elements of a risk. It cannot, in any justice, be excluded after death. How then diminish it as much as possible? Simply by excluding it as much as possible *before* taking the risk.

Let the companies have well-paid and competent medical officers. Let no medical officer be in any sense of the word a solicitor, or interested in soliciting. The medical examination should be entirely private as between the physician and applicant; and, after failing to detect any present obstacle to acceptance, should reasonable doubt arise in the mind of the examiner as to the truthfulness of the statements made to him in regard to history, habits, predisposition, occupation, etc., he should suspend judgment, and seek information from all outside sources at command. In this search he should be cheerfully aided by the officers of the company, and not impeded, as is well known to be sometimes the case, by those who are pecuniarily interested. By these means the nearest approximation to safety will be attained.

Perfection and prescience are not attainable. Examiner and applicant are alike human; but see that the first is the best you can command, and if the latter deceives him, it is part of the risk.

The happiest man of to-day may become a suicide in a year; the most temperate one may die a drunkard; the most loathsome diseases may be contracted in a night's debauch. Who is to tell? The divine power only can separate the sheep from the goats. The "selection of the fittest" is the only guide for the examiners; and for these reasons I maintain that when once a risk is underwritten the responsibility is assumed, and there is no escape.

H.

CORRESPONDENCE.

LONDON LETTER.

[*From Our Own Correspondent.*]

The Anatomical Relations of Tubercle—Debate in the Pathological Society of London—Characteristics of English Medical Debates—The Principal Speakers—Is Tubercle specific in its Anatomical Characters or its Origin?—Proposed Abolition of the Term "Tubercle"—Insufficiency of Anatomical Characters—Death of Dr. Bence Jones—of Professor Partridge—of Baron Liebig.

LONDON, April 26, 1873.

THE great discussion on the anatomical relations of tubercle initiated at the Pathological Society of London has been brought to a conclusion, after three sittings, the whole of which were devoted to it. It has extended over so wide a field, and has occupied so many different parts of the field, of pathological and clinical observation, that it is quite impossible to present an intelligible summary of it within the space of a letter, and I can only refer to a few points of interest in connection with it. The whole debate, however, will, I believe, appear very shortly in a verbatim report which is about to be published in pamphlet form, and I dare say it will find its way to your side of the Atlantic, so that those of your readers who are sufficiently interested in the subject to desire to read what are the opinions of the leading authorities in this country on existing doctrines of tubercle will easily be able to do so in the words of the respective speakers.

The leading speakers have been Dr. Wilson Fox, the Professor of Pathology in University College; Dr. Charlton Bastian, F.R.S., of the same college; Dr. J. H. Green, of Charing Cross Hospital; the veteran Dr. C. J. B. Williams, Dr. Lionel Beale, Dr. Cayley of Middlesex Hospital, Dr. Payne of St. Thomas's, and Dr. Moxon of Guy's. These are the flower of our pathological schools, and they have drawn crowded houses every night. At first it was proposed to impose arbitrary limits of time; for the ordinary rule of the Pathological Society is that no speaker is allowed more than ten minutes, or, at most, twenty minutes; and the latter limit is usually very rigidly observed. But on this occasion, in deference to the strong opinion of the members unofficially or semi-officially expressed through a leading medical journal, the rule was suspended; and, although the speakers on this almost interminable subject were besought to observe brevity to the utmost of their power, no limits were imposed. The whole tendency of our English societies is, however, to discourage orations; there is always observable a nervous desire to avoid oratory on the part of the speakers, and a great impatience of anything approaching to it among the auditors. Short, dry statements of unadorned facts and arguments are what is expected, and nothing else is tolerated. Hence we have not among us more than two or three orators; and these are always careful to repress their capabilities in speaking at the medical societies, and only display their powers elsewhere. Sir James Paget is a born orator; so are Sir Thomas Watson and Sir William Gull and Mr. Savory; but they are rarely heard at the societies in more than a few sentences, delivered in a studiously subdued monotone and with a deliberately passive manner which excludes all gesture. When occasionally a foreign orator, such as M. Ricord or Demarquay, or M. Labbé (recently), has addressed English meetings of medical men, as at the last meeting of the British Medical Association, it has been curious to observe the half-startled, half-amused expression of their listeners, as they poured forth their orations with animated gestures, in high-pitched notes, and with the artifices of interrogation, response, protest, sarcasm, and voluble argument which belong to the trained speaker who expects his auditors to follow him by the hour together.

The habits of a lifetime are not easily overcome; and hence in this set debate, in which something of oratorical grace would neither have been ill placed nor unpleasing, there was very little of the kind to relieve the dryness of a very abstruse discussion. It was thoroughly English in its sobriety, earnestness, and solidity,—and also in its dulness. But nevertheless the audience felt that they were being instructed; no one was speaking for effect, or attempting to cover thinness of matter by volubility of manner, and they were well satisfied. Sir William Jenner, the president, shrank from the task of summing up the far-reaching debate; and I may hardly be expected to attempt what he felt to be beyond his critical powers. The various journals have essayed it; but, as each of their summaries extends to eight or ten columns, their example is not encouraging. Perhaps the most available is that in the *Medical Times* of April 20. The writer says, "This much in the discussion was patent to all. In the lungs of children dying of acute tuberculosis are to be found certain changes which may be taken as typical in all important respects of the changes of the same organs in phthisis. These changes consist in the development of cells of an epithelial and lymphatic type, with a greater or less tendency to fibrillation, and after the death of the cells to caseation. Is this tubercle? Is it specific or characteristic? What is its etiology? and is it the only essential change in a phthisical lung?

"Some denied the specific nature of tubercle altogether, and others said it was specific as regards its life-history, but that there was no characteristic structure whereby it could be recognized; others still concerned themselves in discussing words and definitions. Some went so far as to propose to do away with the name tubercle altogether: how many would bless them if they could as easily do away with the thing to which the name is commonly applied! An attempt was made to elevate the existence or absence of 'giant cells' into an important criterion of the structure of miliary tubercle, but it was not generally adopted. Undoubtedly such do exist; but their exact meaning is yet far from clear. Another question which arose was, how far we were justified in extending the term tubercle to the infiltrations sometimes found along with the small gray granulations. Well, if there is no perceptible difference in structure between the two,—if the one merges insensibly into the other,—it is hardly possible to refuse the same name to both, even although there exists a tendency to aggregation in small nodules in the one which is not seen in the other. But perhaps the most important part of the discussion was, whether the growth called tubercle was specific or the result of ordinary inflammatory changes. All seemed to admit that the process ordinarily called inflammation had something to do with the production of the changes seen in phthisis; but most seemed to think also that the process called tuberculosis, ending in the production of a distinct growth, had more. Had, then, this tubercular growth any origin apart from the origin of the inflammation? was any specific irritation necessary to set it up? or was it only a question of degree, whether the large- or small-celled growth was the result? Most seemed to think that some such specific cause was necessary, but were not inclined to say wherein it consisted, though some thought it could act both locally and from a distance. Some seemed to think that caseous matter was the source of infection; but others, again, that in certain imperfect constitutions any irritations might give rise to the peculiar growth they called tubercle."

In the absence of any summing up, these questions cannot be considered to have been decided; but the general result of the discussion has been, I think, to produce the opinion that Dr. Bastian is right in advocating the disuse of the word "tubercle," inasmuch as "there is no anatomical structure which can be fitly established, under the name of tubercle, as the proper basis of phthisis in every kind." Miliary deposits are looked upon as, and indeed shown both by Bastian and Green to be, merely the results of an infective process; and the giant cells of Schüppel which have been investigated, and even shown by Bastian and Cayley, are believed to be not more characteristic, but rather to be the result of chronic indurative inflammation in tissues intimately connected with the lymphatic system.

Dr. Anstie, who writes the *Lancet* articles on the subject, while admitting as the result of the debate that the word "*tubercle*" ought to disappear from pathological nomenclature, doubts whether "*granulie*" proposed by Bastian (after Empis) ought not to be employed as synonymous with "tuberculosis" to express simply the important clinical facts which are bound up in the acute febrile disease attended with greater or less diffusion of granular deposits, including, nearly always, granulations (usually fatal) of the cerebral meninges. Dr. Aufrecht has just issued a monograph in which he seems to employ it;* and, patronized by active workers in France, Germany, and England, it is likely to come into favor.

No doubt also the discussion has tended to show that merely histological investigations do not suffice to differentiate "tubercle" as a disease from other diseases, and that, altering our pathological views, we must rely more than has been the tendency of late years upon clinical lines of distinction. On the whole, I think this debate will be found extremely interesting to pathologists and physicians generally, and not unworthy of the reputation of the Pathological Society of London.

I fear I have left myself little room to advert to any other topics in this letter. We have, I may however mention, had to deplore the death of Dr. Bence Jones, F.R.S., well known as a highly eminent physician of the chemical and philosophical school in connection with the study of diseases of the kidneys and digestive organs. Married to a lady of title and fortune, early achieving the position of senior physician of St. George's Hospital, the pupil of Liebig, friend and biographer of Faraday, and Honorary Secretary to the Royal Institution of Great Britain, he filled a large and useful place in the promotion of biological science, both

* Die chronische Broncho-pneumonie (Lungenschwindsucht) und die Granulie (Tuberculose). Eine Skizze. Von Dr. E. Aufrecht.

by his example and influence; and his death, from heart-disease, is greatly regretted.

Mr. Partridge, the senior surgeon of King's College Hospital, and late President of the College of Surgeons, is also dead. He came prominently before the public many years ago as having conceived just suspicions and effected the arrest and conviction of Burke and Hare, the famous "resurrectionists," who had supplied the medical schools of London with many hundreds of subjects for dissection, and brought to King's College the body of an Italian street-beggar who displayed for pence a few white mice. This lad they had murdered; and when they were apprehended and about to be tried on rather defective evidence, Mr. Partridge succeeded in obtaining an important circumstantial piece of testimony by suggesting that a trap should be set in their room, in which, accordingly, the white mice belonging to their victim were presently caught. He was also rather unfortunately prominent a few years since as having been summoned to the aid of Garibaldi when wounded at Aspromonte, and having failed to detect the bullet which Nélaton afterwards found lodged in the bones of the ankle, diagnosing its presence by the aid of the famous porcelain probe.

The death of Baron von Liebig is announced here; and, as the great chemist was a frequent visitor to this country, and published here many of his papers on chemical and industrial subjects, and was much respected, many warm tributes of friendship and esteem are published in the daily papers as well as in the chemical and medical publications. His last addition to our food-resources is so popular here that it is common enough to hear a person invited to drink a cup of "Liebig," by which is meant a cup of beef-tea made with his extract of meat, or to hear of soups and sauces made with "Liebig."

I fear neither Mr. Partridge nor Baron Liebig died wealthy. Mr. Partridge, although enjoying very high official positions, had not for many years possessed a lucrative practice. Recently he was President of the Royal Medical and Chirurgical Society, the senior medical society of this country, and, in accordance with the annual practice, issued cards for a full-dress dinner to the Council. A week after their issue, however, the dinner was "unavoidably postponed;" and it was never given. This caused some little gossip at the time; but I believe Mr. Partridge leaves now only a very few hundred pounds. It is sad to see how many eminent men have, or think they have, to spend nearly the whole of their income in "keeping up their position," and how often their later years are ill provided for.

St. Louis, May 9, 1873.

To the Editor of the Philadelphia Medical Times:

DEAR SIR:—The newspaper reports of the doings of the American Medical Association are so full as to require little to be said on my part. I shall therefore merely give you the impressions made by the convention which has just adjourned. It seemed to be the universal regret among the profession here that the Association chose to convene at St. Louis at a time when the city was in a condition to display itself to the least advantage. The small number and crowded condition of her hospitals, the unsettled state of her medical societies, rendered the profession fearful lest the impression might be conveyed that she had fallen back in the onward march towards the establishment of a more thorough change in the advancement of the study of medical science. Far from this being the case, everything has been done to place St. Louis foremost among the medical centres of the country. Large hospitals are being erected, and plans are proposed to attach them to the colleges for the purpose of furthering clinical instruction. The kind reception met with by the delegates from the profession proved the fact that whether the meetings of the Association have a tendency to promote the advancement of medical science to any degree or not, they certainly are of great utility by drawing together the medical men from all parts of the Union, encouraging the free interchange of opinion, and bringing the profession before the public as a body of learning and intelligence.

I am safe in saying that, so far as I can determine, the feeling among the delegates was that little if any apparent scientific advancement was accomplished during the convention. True it is that a foundation has now been laid, upon which the Association may rest in future more firmly. The formation of a judicial body, as you will see by the report, was certainly a desideratum, and the referring of miscellaneous matters to appropriate sections rendered the sessions far more useful. The five sections were as follows: Surgery; Practice of Medicine and Obstetrics; Psychology and Medical Jurisprudence; Chemistry and Materia Medica; Climatology and Public Hygiene. The sections seemed to accomplish little; their sittings were nearly always characterized by a lack of energy and interest on the part of the few members in attendance. So obvious was this on the second day that attention was called to it at the public meeting of the Association on the following morning. The surgical section was the most largely attended; as for the one on chemistry and materia medica, owing to the small attendance, it was often difficult to find. A subject for general remark was the non-attendance of many members, whose position renders them prominent in the Association, from Philadelphia and New York. Was it, it was asked, that the Association was being abandoned by its older members, or were these men gradually alienating themselves from an active part in the proceedings, and substituting strangers in their stead, at a time when of all others they were most needed?

The attendance was quite large, over four hundred delegates being registered by the evening of the first day. The meetings of the Association, which were held in the mornings, were characterized by a cordiality among the members, and a freedom from violent discussion, which rendered them better able to dispose of the subjects which came up for their consideration. It

seemed really as if the meetings of that staid and deliberate body were for the purpose of giving the delegates a frolic,—of relieving them for a few hours from the toils of their professional work. As far as that was concerned, the twenty-fourth annual convention was decidedly a success.

The Association of Medical Editors, which convened on Monday evening, was addressed by Dr. Parvin. The entire address, published two days after, I send you. The meeting was very poorly attended, about fifteen gentlemen only being present. The committee on prizes being absent, the distribution of the awards for the best essay was deferred.

Very respectfully yours, K.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, April 23, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

PHLEGMASIA DOLENS.

DR. A. P. TEN EYCK addressed the Society upon this subject. He remarked that it was comparatively a rare disease, most commonly confined to parturient women, though unmarried females and males were sometimes thus afflicted, and referred to two cases mentioned in Druitt's Surgery where it occurred in men. He was of the opinion that, as it so seldom attacked the male sex, it should be classed as a disease peculiar to females.

It was explained as being an inflammation of the femoral vein, produced by the various influences incident to childbirth, as the unskilful use of instruments, too early getting up, cold, etc. It frequently occurs without apparent cause, as illustrated by a case about to be mentioned. The pathological state has been differently described by writers: the older authors supposed the tumefaction was due to milk deposited in the affected limb, which idea gave rise to the name of milk-leg; but, now that its true nature is better understood, these names have been abandoned, and the name phlegmasia alba dolens adopted.

Dr. TEN EYCK remarked that the affected leg had a peculiar milky-white appearance, and the lacteal secretion, however copious before the attack, is afterwards diminished or entirely abated. These facts might well justify the name milk-leg, which has been adopted in unprofessional as well as in professional parlance.

Mrs. R., æt. 24, of medium size and fair complexion and inheriting a good constitution, married, became pregnant, and aborted during the third month from a severe fall. In eight months more she again conceived, and went on to full term before confinement, when she was delivered of a large-sized child without offering any obstacle to a safe and easy delivery. No untoward symptoms presented after confinement. The next day she complained of headache, which continued more or less for the next two weeks, the lacteal secretion being rather scanty; the lochial discharge was normal.

Thirteen days after delivery she complained of pain in the left groin and hip and in the calf of the leg. There was no chill or any symptom of fever preceding this pain. The pain grew severe, the patient became restless, appetite impaired, tongue slightly coated, pulse 120, and in seven days more the limb was much swollen. The pain, swelling, and pulse continued to increase; the lacteal secretion diminished, but the lochia remained about the same.

Upon the thirteenth day all of the symptoms were aggravated, pulse 140, pain excruciating, swelling enormous from the ends of the toes up to the body, and even the abdomen was enlarged and tender. The labium majus on the affected side was swollen so much as to render micturition difficult. The limb had the characteristic tense shining-white appearance of the disease, and the femoral vein could be felt under the finger like a whip-cord. The bowels were but slightly constipated, skin moist, and the tongue but slightly coated. On the twenty-sixth day the lacteal secretion was entirely suppressed, and the pulse still continued 140.

In a little more than a month there was an abatement of the symptoms, with a diminution of the pulse and swelling, which gave encouragement of recovery; but his improvement was only deceptive, for in eight hours more the pulse rose to 160, with great increase of pain, but on examination the first limb attacked was nearly of normal size, but the other was enormously swollen; the labium on this side was now swollen as had been its fellow, and the same inconvenience in urinating followed. In the track of the femoral vein some portions assumed a livid hue, and the doctor feared that a sphacelous condition would ensue. After a few days these threatening symptoms passed away, and the case progressed in a favorable manner; but the pulse never fell below 130 until three months after the attack. About this time an eruption resembling that of smallpox made its appearance. Between the pustules the limb was scarlet. This condition lasted two weeks; both limbs were covered with the eruption. In the course of four months she was sufficiently recovered to walk across the room without support.

Dr. TEN EYCK then referred to the treatment, after making mention of the treatment of others as published in medical journals. He remarked that in his case he supported the system and administered anodynes to relieve pain. Iron and quinine were used as a tonic; the bowels were occasionally regulated with Seidlitz powders. As local applications he used a weak solution of carbolic acid, applied hot, to the first limb affected, but to the second limb attacked he used thirty grains of sulph. ferri to the ounce of water, as hot as could be borne to the limb, it being bandaged from the body to the toes. This seemed to give better satisfaction and to give more relief than any thing else, the only objection to its application being its permanent stain to the clothing.

Dr. JAMES S. BAILEY said that he had seen an unusual number of cases of this disease, and that four cases had occurred in his own practice, in the first seventy-five cases of midwifery that he had attended, in the year 1871. In three cases it only appeared in one leg; in one case in both legs, first one and then in the other: one of the women was a primipara, the other three multiparæ. The woman in whom it occurred in both limbs was delivered of twins. She died in the course of three months, from exhaustion. He regretted that he could not obtain the consent of the friends to a post-mortem examination.

The plan of treatment adopted was to support the system, keep the bowels regulated, give anodynes to relieve pain and procure rest, and to wrap the affected limb in flannel cloths wrung out of hot water and applied as warm as could be borne, and this dressing covered with oiled silk. These applications were continued until all signs of inflammation had subsided.

Dr. S. H. FREEMAN remarked that he had occasionally in his practice met with cases in females of lymphatic temperaments with light complexions, and had used

spirits of turpentine freely, but with care, to the affected member. In one case, occurring not long since, the nurse had used it rather lavishly, and it had produced vesication, after which he had wrapped the limb in cotton batting and covered this with oiled silk. The case did well, and recovered in three weeks.

Dr. F. C. CURTIS said that Prof. Thomas, of New York, recommended a vesicant along the course of the vein, at one side of it.

Dr. E. H. DAVIS said that he was much pleased with the paper just read, and regarded the subject of phlegmasia dolens as well worthy of the consideration of the Society. He had seen quite a number of cases, and had observed its onset, course, and termination; was not prepared to say that it is or is not a disease of the femoral vein; but, with his views of what constitutes phlebitis, he did not think that inflammation of the femoral vein was the exclusive cause of the disease, but was inclined to the opinion that the inflammation involved the veins, lymphatics, muscles, and cellular tissue; but regards its pathology as still unsettled. The treatment depended upon the general condition of the system. In case of plethora and fulness, with violent inflammatory symptoms, he would not hesitate to bleed; but, in an opposite condition of the system, quinine, with other tonics, might be early necessary. The local application of the hot infusion of hops had been found very serviceable in his practice, followed later by stimulating embrocations.

(To be continued.)

OBITUARY.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,

WASHINGTON, May 5, 1873.

THE Surgeon-General announces with regret to the Medical Corps the death of one of its senior members, Surgeon and Brevet Brigadier-General Madison Mills, which occurred at Fort Columbus, New York Harbor, on the 28th of April.

Receiving his commission as Assistant Surgeon, U.S.A., in April, 1834, Surgeon Mills's service extended over a period of thirty-nine years, during which it was his fortune to take part in the Florida war, the war with Mexico, the Utah Expedition of 1858 (as Medical Director), and the war of the Rebellion. He was Medical Director of the Department of Tennessee (General Grant's Army) at the time of the siege and surrender of Vicksburg, and in December, 1864, was appointed Medical Inspector General, the duties of which position he discharged most satisfactorily. In November, 1864, the brevets of Lieutenant-Colonel and Colonel, and in April, 1865, that of Brigadier-General, were conferred upon him for faithful and meritorious services.

Possessed of unflinching determination and courage, and guided by professional abilities of a high order, his administration of the trusts confided to him was marked by a prompt efficiency and sound judgment that secured successful results, even under the most adverse circumstances.

J. K. BARNES,
Surgeon-General, U. S. Army.

ELIMINATION OF SALTS OF MERCURY.—M. Byasson is quoted in *Le Mouvement Médical* for March 22 as announcing the following conclusions: The bichloride of mercury taken by the mouth may be detected in the urine about two hours afterwards; it appears in the saliva about four hours after its ingestion. It has not been found in the sweat. Twenty-four hours after the swallowing of a dose of this article, it may be considered as eliminated.

GLEANINGS FROM OUR EXCHANGES.

DR. STIFF (*Boston Medical and Surgical Journal*, April 10; from *Correspondenz-Blatt der deut. Gesell. f. Psychi. u. gerichtlich. Psychol.*, 1872, 11 and 12) mentions a species of optical illusion of which he was the subject during an attack of scarlatina. He saw hunts, numberless wild beasts, followed by as numberless packs of hounds; behind these, innumerable huntsmen; soon again, great masses of troops falling upon one another; at another time processions, herds of slaves, masses of people, etc. Most remarkable, however, was the mode in which these masses were grouped and moved. They arose from two sides and approached, or rather two columns advanced from the same side to meet in the middle, where was an undistinguishable confusion. These phenomena were visible with the eyes shut, and in a dark room. In the light they disappeared. The fashion of the appearance corresponded so exactly to the course of the large vessels of the retina, that he concluded it must be owing to the blood flowing through the veins, and that the sight of the various figures was dependent upon the impression made by the blood-corpuscles moving through the veins to the papilla, where was the confusion of all forms. He questions whether the phenomena seen during delirium tremens may not sometimes be of this nature.

THE THIRD INTERNATIONAL MEDICAL CONGRESS, TO BE HELD IN VIENNA (*Wiener Med. Presse*, April 13, 1873).—The Third International Medical Congress will be under the protectorate of his Royal Highness the Archduke Rainer.

I. The Congress is to assemble in Vienna, during the "World's Fair" in that city, and will remain in session from the 1st to the 8th of September, 1873.

II. Members of the Congress are: 1. Members of the Executive Committee already appointed to make preparations for the Congress. 2. Delegates from governments or from scientific corporations,—universities, academies, medical societies, and hospitals. 3. All physicians and scientific men who announce themselves before the day of the opening of the session as prepared to take part in the Congress.

III. There will be no tax levied upon the members in the Third International Congress.

IV. The sittings of the Congress are to be public. The Executive Committee and the medical societies of Vienna will attend to arranging the members into departments devoted to special scientific subjects.

V. All the members of the Congress have a right to discussion, and a vote.

VI. The programme of the various sittings is—*a.* Reading of the order of exercises prepared for the Congress by the Executive Committee; *b.* Consideration of questions handed in before the 15th of August, and arranged for given sittings of the Congress.

VII. The questions and points of consideration prepared by the Executive Committee are as follows: *a.* The vaccination question; *b.* The question of quarantine in respect to cholera; *c.* The prostitution question; *d.* Sanitary management of cities; *e.* Propositions for an international pharmacopœia; *f.* Propositions relative to an introduction of a greater conformity in the study of medicine in all countries, and a corresponding right to emigrate and practise where one desires.

VIII. The programme thus decided upon will be distributed to various sub-committees, who shall introduce the subjects with suitable reports.

IX. The president of the Executive Committee is to preside at the first and last sitting of the Congress. At the first sitting the members shall choose chairmen for the remaining sittings of the Congress. The bureau of

the various sittings and for the Congress in general is formed by the members of the Executive Committee.

X. Voting upon scientific questions, as such, shall not occur, but only upon propositions which have for an object the influence of the Congress upon regulations and rules of government in important general sanitary measures.

XI. All voting upon questions proposed by the programme, and all elections, shall be by ballot.

XII. The language used in the Third International Medical Congress shall be the German; yet other languages will be allowed. The communications from the Executive Committee shall be in German, accompanied by French, English, and Italian translations. The same holds good for the publication of the various acts of the Congress.

XIII. In the sitting preceding the last, the place for the meeting of the Fourth International Medical Congress will be decided, and the Executive Committee for it appointed.

XIV. The proceedings of the Congress are to be subsequently published and sent to the members.

VIENNA, March 1, 1873.

ORDER OF BUSINESS FOR THE THIRD INTERNATIONAL MEDICAL CONGRESS, TO BE HELD IN VIENNA (*Wiener Med. Presse*, April 13, 1873).

1. The sittings of the Congress shall occur daily (Sunday excepted), in the forenoon, from 9 until 1 o'clock.

2. Each member shall receive a printed programme of business, a number of ballots containing his own name, and one ballot for each question to come before the Congress:

a. For the choice of presidents for the single sittings.

b. For the choice of place for the Fourth Congress.

c. For every question introduced by the programme of the Executive Committee. Sec. XI. of the statutes.

3. The results of each vote will be collected, so as to make known the vote of each delegate.

4. Communications are to be heard only when made by the author. Communications sent to the Congress are to be read in a special session appointed for that purpose, and copies distributed to the members, if copies are sent to the Congress by the authors.

5. No speaker may occupy more than fifteen minutes, unless specially allowed by the meeting.

6. During the session of the Congress the executive will publish a daily announcement of subjects of interest to the members, and this shall be distributed among the members.

7. The protocol of the Congress will contain only those papers, in part or in whole, which have been handed to the General Secretary in a proper shape.

8. The collection and publication of the official report of the transactions of the Third International Medical Congress is the duty of the General Secretary.

VIENNA, March 1, 1873.

POSITIONS FOR CATHETERISM.—Mr. Teevan, Surgeon to West London and St. Peter's Hospitals, says, in the London *Lancet* for February 15, 1873, that the sitting position is best for the surgeon and the standing best for the patient. The following are some of his reasons:

"However prolonged the operation may be, the surgeon will not become fatigued. . . . It is the one position in which he enjoys the maximum amount of mobility with the minimum of power, and is therefore the one position in which he is least likely to make a false passage. . . . If the surgeon adopts the sitting position, I feel convinced that he will, in the long run, prove a far more successful operator than one who stands, and that he will often succeed where the latter has failed."

In the patient, "what we desire is fixity, and we shall best achieve this object by placing him upright against the wall and stretching his penis horizontally forwards. So situated, we have at last obtained all that can be desired; for the urethra, instrument, and direction of force are all in the same horizontal and vertical plane, and our axis of vision will nearly correspond. Thus, therefore, we shall be able to impress on the point of the catheter, when lost to view, any direction we may desire it to seek, and our operation will no longer be an exhibition of blind and unguided force, but a successful demonstration of applied skill."

MISCELLANY.

GERMAN STUDENTS IN THE LATE WAR.—An interesting work has just been published at Leipsic, giving an account, by a German student, of the part taken by members of the different German universities in the late war, of the services performed by those of the medical profession under the red cross, and biographical notices of 248 students and 4 professors who fell in action. The University of Leipsic suffered the greatest loss,—63 members in all. The losses of the other universities were as follows: Berlin, 30; Göttingen, 23; Munich, 21; Halle, 19; Heidelberg and Jena, each 13; Breslau, 11; Bonn, 9; Tübingen, 8; Rostock, 6; Greifswald, Kiel, Königsberg, and Würzburg, each 5; Marburg, 4; Giessen, 3; Freiburg and Münster, each 2; Erlangen, 1. Out of the 13,765 German students matriculated in the summer term of 1870, 4510—that is, a third—went through the campaign, about 3500 of whom were in the ranks, and 1000 attached to the ambulances. Out of 1505 university professors, 15 were under arms, 253 devoted themselves to the care of the sick and wounded, and 120 worked for the national cause by speech and pen.

THREE journals devoted to sanitary matters have recently been started. Of these *The Sanitarian*, published in New York, under the editorship of Dr. A. N. Bell, is the most promising. There is certainly much need for the discussion of these subjects; but perhaps the end would be as completely answered by publications in journals devoted to the general interests of medical science.

INTERNATIONAL COMPLIMENT.—Last winter Dr. Acland, F.R.S., LL.D., Regius Professor of Medicine in the University of Oxford, and honorary physician of the Prince of Wales, was elected a member of the American Philosophical Society of this city; and recently a similar compliment was conferred upon him by the Academy of Medicine of New York.

SURGEON-GENERAL BARNES, of the United States Army, was recently one of three nominees for a vacant corresponding membership in the Paris Academy of Medicine. The ballot, however, resulted in the election of Mr. Prescott Hewett, a British surgeon of eminence.

AT a late meeting of the Obstetrical Society of London, Drs. Fordyce Barker and T. Gaillard Thomas, of New York, were elected Honorary Fellows of the Society.

NOTES AND QUERIES.

"EAR-COUGH."—"Ear-cough," so named by Dr. C. B. Fox, of Scarborough, England, is caused by irritation applied to the external auditory meatus. This irritation is most probably communicated through the auricular branch of the pneumogastric nerve to the lungs, and hence the cough.

I have under observation several cases of this cough in patients affected with chronic catarrh and adhesions in the middle ear. In two cases the irritation can be produced only through *one* ear. In a case where I performed paracentesis of the membrana tympani through a cicatrix in the posterior portion of the membrane, severe "ear-cough" was excited, and lasted five minutes. This was the *only* unpleasant symptom caused by the operation, there being no bleeding nor pain. If "ear-cough" is created by excitation of the pneumogastric nerve (Romberg and Toynbee), a cough may also be excited in the same person, who, without doubt, possesses a peculiar susceptibility to irritation of the pneumogastric nerve, and consequent coughing, by the administration of quinine, as in Dr. J. Solis Cohen's case (*Philadelphia Medical Times*, No. 79, 1873). This fact, related by Dr. Cohen, would seem to indicate that "ear-cough" is caused by an irritation of the pneumogastric nerve, rather than by "a sympathetic communication between the larynx and the ear by means of the auriculo-temporal branch of the fifth cranial nerve" (C. B. Fox), since a cough "exactly similar to the 'ear-cough'" was induced by the administration of quinine, which, without doubt, irritated the vagus.

Conium in the Treatment of Insanity. By Daniel H. Kitchen, M.D., Assistant Physician of the New York State Lunatic Asylum. (From the *American Journal of Insanity* for April, 1873.) 8vo, pp. 24.

Civil Malpractice. A Report presented to the Military Tract Medical Society at its Fifteenth Semi-annual Meeting, January 14, 1873. By M. A. McClelland, M.D. 8vo, pp. 74. Chicago, W. B. Keen, Cooke & Co., 1873.

Mineral Springs of North America; how to reach, and how to use them. By J. J. Moorman, M.D., Physician to the White Sulphur Springs, etc., etc. Crown 8vo, pp. 295. Philadelphia, J. B. Lippincott & Co., 1873.

A Treatise on the Principles and Practice of Medicine; designed for the Use of Practitioners and Students of Medicine. By Austin Flint, M.D., etc. Fourth Edition, Carefully Revised. 8vo, pp. 1070. Philadelphia, Henry C. Lea, 1873.

The Passions in their Relations to Health and Diseases. Translated from the French of Dr. X. Bourgeois, Laureate of the Academy of Medicine of Paris, etc., by Howard F. Damon, A.M., M.D. Small 8vo, pp. 201. Boston, James Campbell, 1873.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 6, 1873, TO MAY 12, 1873, INCLUSIVE.

MILHAU, J. J., SURGEON.—Relieved from duty in Department of the South, and assigned to duty as Post Surgeon at Fort Columbus, New York Harbor. S. O. 94, A. G. O., May 7, 1873.

ALDEN, C. H., SURGEON.—When relieved by Assistant-Surgeon White, to avail himself of the leave of absence granted in S. O. 56, c. s., A. G. O. S. O. 52, Department of the Lakes, May 6, 1873.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, and to report in person to the Commanding General Department of the Columbia, for assignment to duty. S. O. 94, c. s., A. G. O.

WHITE, R. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Porter, N.Y. S. O. 52, c. s., Department of the Lakes.

WILSON, W. J., ASSISTANT-SURGEON.—Granted leave of absence for thirty days on Surgeon's Certificate of Disability. S. O. 66, Department of the Missouri, May 4, 1873.

KING, J. H. T., ASSISTANT-SURGEON.—Assigned to duty at Fort Brady, Michigan. S. O. 53, Department of the Lakes, May 9, 1873.

WEEKLY RETURN OF DEATHS AND INTERMENTS IN PHILADELPHIA FOR THE WEEK ENDING SATURDAY, MAY 10, 1873.

METEOROLOGICAL OBSERVATIONS TAKEN AT THE SIGNAL OFFICE, PHILADELPHIA, DURING THE WEEK ENDING SATURDAY, MAY 10, 1873.

Month and Day.	*Barometer. Daily Mean*	*Thermom. Daily Mean*	*State of Weather.*	*Rain. In.*
MAY.				
Sunday 4th	30.06	53	Fair, Clear.	.....
Monday 5th	30.15	59	Clear, Fair.	.....
Tuesday 6th	30.35	55	Clear, Fair.	.....
Wednesday....7th	30.36	52	Cloudy, Fair.	.....
Thursday....8th	30.20	48	Rain.	.43
Friday 9th	29 99	50	Light Rain, Clear.	1.50
Saturday 10th	30.03	54	Cloudy, Fair.	.....
Means	30.16	53		1.93

The surface of the cistern of Barometer is located 71.92 feet above the mean level of the sea.

Barometer corrected for temperature, elevation above sea, and instrumental error.

SATURDAY, MAY 24, 1873.

In order to place before our readers, without delay, a full report of the proceedings of the American Medical Association at its recent meeting, we have been obliged to change, for this week, the arrangement of the *Times*. Our next issue will be in the usual form.

PROCEEDINGS OF THE AMERICAN MEDICAL ASSOCIATION, TWENTY-FOURTH ANNUAL MEETING.

HELD AT ST. LOUIS, MISSOURI, MAY, 1873.

First Day.

THE Association was called to order at eleven o'clock, May 9, by Dr. D. W. Yandell, of Louisville, the retiring President, who introduced Rev. Dr. Niccolls, who opened the meeting with prayer. Dr. John S. Moore, of St. Louis, then delivered an address of welcome to the members of the Association, on behalf of the medical profession of the city.

Dr. Yandell then introduced the President of the Association, Dr. Thomas M. Logan, of Sacramento, California.

Dr. J. B. Johnson, the chairman of the Committee of Arrangements, supplemented the welcome of Dr. Moore, and presented the report of the committee, announcing the following order of exercises: Presentation of the list of delegates and permanent members for confirmation. (The secretary then read the list of those who had registered.) The committee recommended the hours of meeting from 9.30 to 1.30, the sections to meet from 3 to 5 P.M. In the evening there would be a musical soirée at Mercantile Library Hall, to which the members of the Association and their ladies were invited. On Wednesday evening there would be a soirée at the residence of Colonel J. L. D. Morrison. On Thursday evening Dr. J. J. Woodward, of Washington, D.C., would deliver the Toner lecture, on cancer, in the main hall, illustrating it by exhibitions of microscopical views. On Friday afternoon there would be an excursion to Tower Grove Park and Shaw's Garden, carriages to be in readiness at the hall at 2 P.M. A letter to the President of the American Medical Association, upon the standing of the medical corps in the army, was announced as the order of business for eleven o'clock this morning. A letter was read from Postmaster Filley, announcing that a letter-box had been provided at the hall for the convenience of delegates, and that letters would be collected by the carriers. Also, that members leaving their address with the Secretary could have their letters delivered at their lodging-places or at the hall, as they might desire. In conclusion, Dr. Johnson moved that the names of those who desired to be accredited as delegates, but against whose reception protests had been filed, be referred to the Committee on Ethics. The motion was carried, and the President nominated as such committee Drs. N. S. Davis, E. L. Howard, H. F. Askew, D. W. Yandell, and J. M. Toner.

Dr. Logan then delivered his address. He alluded to the meeting of the Association in San Francisco, two years ago; to the influence of this body in raising the standard of preliminary education for physicians, and in quickening the energies of the profession; to the prevalence of skepticism on the subject of therapeutic means; to the possibility of placing medicine among the exact sciences; to the elevation of its followers in the estimation of the public by the diffusion of correct sanitary and hygienic principles; and advocated a return to the plan of meeting every two years at the national capital.

Second Day.

The Association met at half-past nine o'clock, President Logan in the chair.

The attendance was largely augmented, many physicians having reported and registered during the previous evening.

The Convention was called to order by the President, and the business commenced by the presentation of an invitation from Mr. Dyer, librarian of the Mercantile Library, which was read by the Secretary, Dr. Atkinson, inviting the members to visit the library at their pleasure.

On motion, the invitation was accepted.

COMMITTEE ON NOMINATIONS.

The President recommended that each State appoint a delegation to represent them in the Committee on Nominations. The roll was called, and the following gentlemen were named by their delegations respectively:

Arkansas, A. L. Brysacker; Alabama, G. Moses; Connecticut, W. A. Wainwright; District of Columbia, F. Howard; Georgia, J. P. Logan; Illinois, H. A. Johnson; Indiana, W. H. Meyers; Iowa, A. M. Carpenter; Kansas, D. W. Stormont; Kentucky, R. H. Gale; Maine, A. Garcilon; Maryland, S. P. Smith; Massachusetts, L. F. Warner; Delaware, H. F. Askew; Michigan, W. Brodie; Minnesota, A. B. Stuart; Missouri, J. B. Johnson; Mississippi, J. W. M. Shattuck; New Hampshire, E. F. McQuesten; New Jersey, S. Lilley; New York, H. W. Dean; North Carolina, R. J. Hicks; Ohio, A. Dunlap; Pennsylvania, W. J. Asdale; Rhode Island, L. Morton; Tennessee, W. T. Briggs; Texas, D. R. Wallace; Virginia, T. D. Cunningham; West Virginia, G. Baird; Wisconsin, E. P. Russell; United States Army, B. A. Clement; United States Navy, E. Eversfield.

The committee then retired to prepare their report.

RECOMMENDATIONS FOR MEMBERSHIP.

Dr. J. B. Johnson, Chairman of the Committee of Arrangements, recommended a number of gentlemen for membership.

Dr. Dix, of Illinois, moved that the names of members by invitation be referred back to the committee.

Carried.

ARRANGEMENTS OF SECTIONS.

Dr. E. L. Howard, Chairman of the Committee on Organization, read a very lengthy dissertation on the necessity of *brevity* in the "section" discussions. He suggested the appointment of sub-committees to whom should be referred all lengthy documents brought before the section.

THE NEXT ANNUAL MEETING.

An invitation was received and read, from Dr. William Brodie, asking that the Association hold its next annual meeting in Detroit, Michigan. Referred to the Committee on Nominations.

Dr. Bronson, of Massachusetts, desired that the report of the Special Committee in reference to arrangement of sections be completed. It was incomplete.

Dr. Davis moved that the report be received, and the recommendations accompanying it be adopted, except such as referred to the code of ethics.

Dr. Porter arose to a question of privilege. He said the code of ethics needed no change; we need improvement. The interruption of time by voluminous

reports worked mischief to the organization. Who reads them? He conceived we wanted improvement in this behalf. We must not make a mountain out of a mole-hill. (Gentle stamping upon the floor, which finally culminated in thunders of applause (?), so that the speaker could not proceed.)

The President suggested that the speaker had exhausted the allotted time for discussion.

Dr. N. S. Davis offered, as an amendment to the by-laws, the following document:

"XI.—JUDICIAL COUNCIL.

"A Council, consisting of twenty-one members, shall be appointed by the Nominating Committee, whose duty it shall be to take cognizance of and decide all questions of an ethical or judicial character that may arise in connection with the Association. Of the twenty-one members of the Council first appointed, the seven first named in the list shall hold office one year, and the second seven named shall hold office two years. With these exceptions, the term of office of members of the Council shall be three years, seven being appointed by the Nominating Committee annually.

"The said Council shall organize by choosing a president and secretary, and shall keep a permanent record of its proceedings. The decisions of said Council on all matters referred to it by the Association shall be final, and shall be reported to the Association at the earliest practicable moment.

"All questions of a personal character, including complaints and protests, and all questions on credentials, shall be referred at once, after the report of the Committee of Arrangements, or other presentation, to the Judicial Council, and without discussion."

Dr. Davis also offered, as an addition to the code of ethics, section twelve, proposing to add addresses, and that three members be annually appointed to deliver addresses on medicine, obstetrics, and diseases of women and children, no address to occupy more than forty minutes in its delivery.

On motion, these documents were laid on the table, and the original report of the committee was adopted.

The following letter from Dr. Gross, of Philadelphia, was read by the Secretary:

"PHILADELPHIA, May 1, 1873.

"DR. LOGAN, *President American Medical Association:*

"MY DEAR SIR,—It is a source of deep regret to me to be unable to attend the coming meeting of our Association. The continued ill health of Mrs. Gross prevents me from leaving home for so long a time as such an absence would necessarily involve. I can think of no greater pleasure than that of shaking hands with you and the rest of our old comrades in the service of the Association and the general interests of the profession. That the meeting, under your dignified and energetic presidency, will be an uncommonly harmonious one, there can be no doubt, and I pray God that no outside or evil influences may be permitted to mar its deliberations.

"I trust that the amendment of the constitution proposed by me a year ago will not be passed by in silence by the Association. If adopted, it could not fail to be an important improvement in our proceedings. We have had, in all conscience, enough reports during the last twenty years upon medical education and medical literature.

"I take the liberty of transmitting to you a copy of the *Philadelphia Medical Times*, containing my views respecting the re-organization of our Association. I believe that if some such plan were adopted it would greatly redound to the credit, the permanency, and the usefulness of the Association. Unless it be placed upon a better footing than it now is, and be made more of a scientific and less of a declamatory body than it has hitherto been, it is easy to foresee that it must be short-lived, and that thus the great object of its founders will be effectually defeated.

"I have the honor to be, dear Dr. Logan, very truly and faithfully, your friend and obedient servant,

"S. D. GROSS."

The Secretary read an invitation from Dr. Prewitt, resident physician of the city hospital, inviting the medical gentlemen to visit that institution during their stay in the city.

The invitation, on motion, was accepted.

Dr. Woodward, Assistant-Surgeon, U.S.A., read the following communication:

THE ORGANIZATION OF THE MEDICAL CORPS OF THE ARMY.

"*To the President of the American Medical Association*:

"SIR,—It is proposed to present, herewith, a brief statement showing that the medical staff of the United States Army has not been placed on an equal footing with the other staff corps of the army as regards rank, that they have not had the same consideration shown them in this respect as has been accorded to the navy, and that the record of services of this meritorious body of officers entitles them to the same advantages that have been granted to others.

"When the rebellion broke out, the medical staff of the army, with a total of 115 officers, had but one of higher rank than that of major, while in the Quartermaster's Department, with thirty-seven officers, five were above that rank; in the Commissary Department, with twelve officers, two were above that rank; in the Adjutant-General's Department, with fourteen officers, two were above that rank; in the Engineers, with one hundred and twenty-nine officers, there were seven; in the Pay Department, out of a total of twenty-eight, there were three; and in the Ordnance, two out of thirty-six.

"The Act of Congress of July 28, 1866, defined the 'Peace establishment of the United States,' and, re-organizing, as it did, with the view of permanence, all the various departments of the army, it might have been supposed that equal justice in the matter of rank would have been meted out to each separate branch of the staff. That this was not the case, so far as the Medical Department is concerned, is shown by the following:

"By its provisions the total number of medical officers was fixed at 217, 7 of whom were above the rank of major, or 3.22 per cent. The Quartermaster's Department was to consist of 76 officers, 17 of whom were above that rank, or over 22 per cent.; the Subsistence Department of 29 officers, 5 being above that rank, or 17 per cent.; the Adjutant-General's Department of 20 officers, 7 being above that rank, or 35 per cent.; the Engineers of 109 officers, of whom 19 were above that rank, or over 17 per cent.; the Ordnance of 64 officers, with 8 above that rank, or 12.50 per cent.; and the Pay Department of 65 officers, 5 being above that rank, or 7½ per cent. It is thus seen that the Medical Department was given a smaller proportion of officers of rank than any other staff department, being less than one-half of that granted to Paymasters, one-quarter of that in the Ordnance, nearly one-sixth of that in the Engineers' and Subsistence Departments, less than one-seventh of that in the Quartermaster's, and about one-twelfth of that given to Adjutants-General.

"The medical officer under the present law is accorded the rank of captain; after three years' service he is promoted to major by seniority, such promotion not ordinarily occurring in less than fifteen years' service; and

that is the end of his prospects of advancement, unless he may be so fortunate as to secure a medical purveyorship, which can necessarily be within the reach of but very few, those positions being but five in number, and vacancies in consequence occurring but very seldom. Not only is this a great injustice to those surgeons on the active list, but it operates still more injuriously towards those old and meritorious officers who, having given their best years to the country, become disabled by age or infirmity and are desirous of availing themselves of the privileges of the retired list. The adjutant-general, quartermaster, or engineer of thirty years' service can almost certainly retire with the rank of colonel, certainly with that of lieutenant-colonel, while the veteran surgeon is laid aside with the rank of major, and an income hardly sufficient to support his station as a gentleman, or to sustain his family.

"The Medical Department is not willing to be accorded a second place in comparison with any other arm of the service. It points with pride to its roll of honor during the last war, to the 38 of its members who were killed in action or died of wounds, to the 12 who were killed by accident in the performance of duty, to the 4 whose lives wasted away in rebel prisons, to the 73 who were wounded in battle, and to the 271 who died from the diseases and exposure of camp-life (an array of figures greater than can be presented by any other staff corps), as a proof that they were always to be found where duty called.

"Without any disposition to make an invidious comparison between the Medical Department and other staff corps, it is believed that at least as high a grade of intellect, as finished an education, as eminent scientific attainments, are required to make an accomplished medical officer as obtains in any other branch of the service. In the case of the vast majority of other staff officers this education is obtained at the expense of the government, which not only furnishes the future adjutant-general or engineer with all the advantages which a scientific school can afford, but actually pays him a handsome salary for four years before he is sufficiently accomplished to render any service therefor. Not so the medical officer. He must obtain his education at his own expense, usually spending years in college, in medical schools and hospitals, before he can hope to be sufficiently qualified to pass the ordeal of an examining board.

"The government cannot expect to obtain the best class of men in any branch of its service unless it offers them equal inducements to those found in civil life. So long as medical men of ability and good scientific acquirements have before them those high prizes which are found in private practice, just so long will they refuse to continue in the army, when no prospect is held out to them of ever rising above a certain grade, or of obtaining beyond a certain amount of income.

"The inducements to engaging in private practice are the prospect of increased income and reputation with advancing years. In the army, these are represented by rank, not only because increased rank carries with it an increase of emolument, but also because to the army officer rank is well and properly understood to enhance the dignity of the person holding it, as well as the respect in which he is held by his compeers and subordinates.

"The rank of medical officers should, therefore, be no less than that of the other staff corps; they require an equal education and equal abilities, they perform equally arduous duties, they sustain as great responsibilities, they are exposed to like dangers, and in the distribution of the rewards of the military career they should be entitled to an equal share. That they are not at present on this footing of equality has been clearly shown in the foregoing comparisons.

"The principles here urged have already been recognized in the recent legislation for the Medical Department of the navy, by which fifteen medical officers were given the relative rank of captain, and fifteen that of commander, corresponding to the rank in the army of colonel and lieutenant-colonel respectively. It is held that no good reason exists why similar promotion should be withheld from the army surgeons, when its necessity has been acknowledged by law for their brethren in the navy.

"The British War Office has likewise recognized the importance of increased rank for its medical officers in the new 'Army Medical Warrant,' and has acknowledged the force of the positions taken in this paper by giving such rank in recognition of long and faithful service.

"A further injustice has been done not only to the medical staff, but to the profession at large, by the legislation which at present forbids any promotions or new appointments in the Medical Department. To the former, because, from the rapid depletion which ordinary casualties make in its ranks, it throws increased labor upon those who remain, and necessitates the employment of physicians under contract, who, having but a temporary tenure of office, cannot be expected to be actuated by that single regard for the service which is a *sine qua non* to the faithful performance of duty. To the profession at large, for it prevents many who are desirous of entering the military service from doing so, and thus perhaps compels them to abandon a design to the accomplishment of which their education may have been especially directed. There are now sixty-one vacancies in the medical staff, fifty-three of them being in the grade of assistant-surgeon. Should promotion be restored, it would then take at least two years to fill the vacancies now existing.

"The result of the continuance of the present state of affairs will be, that many of the candidates for examination, and no doubt the most deserving, will, impatient at delay, seek other channels of usefulness.

"In view of all these facts, it is believed that an appeal made by so representative a body as the American Medical Association, numbering, as it does, delegates living in every Congressional District in the United States, would not be without its effect, and it is earnestly suggested to its members that they will take such action as may seem to them most proper, as will result in placing their professional brethren in the army on an equal footing with those of the navy, as well as with the officers of other staff corps of the army, and also to throw open once more the door for the admission of the young physicians of the country to the ranks of the Army Medical Staff.

and others.

Dr. Woodward said, "Now, Mr. President, I had nothing to do with drawing up this letter, but I indorse it fully, as does also the Surgeon-General. It is understood that by the provisions of the Army Regulations we of the army are debarred from making such an appeal, but we can aid the suggestion verbally, by appealing to you, gentlemen of the Association. Any army officer, except a surgeon, can be retired in old age with a competent pay and the rank of colonel, while a medical man can only have the rank of major after twenty years of service, and may ask for a lieutenant-colonelcy at thirty years. A lieutenant-colonelcy is all we ask. I was an assistant-surgeon twelve years ago, and hold the same rank yet. I have filled my contract with the government, but it has not fully complied with its obligations. We have come up to this convention for help. Will you help us? [Loud applause.] We only ask what was done for our brethren of the Naval Medical Corps, and nothing more."

Dr. Keller, of Louisville, was in favor of asking the government for the aid required for the army doctors.

Dr. Yarnall concurred, but there was one word he wanted omitted, and that was the reference to "rebel" prisons. He wanted that to read "Confederate" prisons.

[We are informed that the change was made.—ED.]

FOREIGN REPRESENTATIVES.

The Secretary read the following appointments made by the President to represent the American Medical Association to the British Medical Association. Drs. F. G. Smith, C. Wister, J. S. Cohen, of Philadelphia; Dr. E. Warren, of Baltimore; Dr. C. L. Ives, of New Haven; Dr. Edward Montgomery, of St. Louis; and Drs. F. Barker, E. Seguin, and J. C. Hutchinson, of New York.

The Secretary stated that commissions for these gentlemen would be made out at once.

REPORT OF NOMINATING COMMITTEE.

Dr. Johnson, of St. Louis, Chairman of the Nominating Committee, made the following partial report:

Your committee suggest the following gentlemen for the various offices named:

President, Dr. J. M. Toner, District of Columbia.

First Vice-President, W. Y. Gadbury, of Mississippi.

Second Vice-President, J. M. Keller, of Kentucky.

Third Vice-President, W. C. Husted, of Missouri.

Fourth Vice-President, L. D. Warner, of Massachusetts.

Treasurer, Dr. Caspar Wister, of Philadelphia.

Librarian, William Lee.

Committee on Libraries, Johnson Elliott.

Secretary, Theodore A. McGraw.

Committee on Arrangements, Dr. Brodie, Chairman; James A. Brown, Morse Stewart, J. F. Noyes, E. W. Jenks, Henry F. Lyster, D. O. Farrand, Eugene Smith; all of Detroit.

Committee on Prize Essays, Drs. J. K. Johnson, A. Sager, H. Hitchcock, of Detroit; E. Andrews, Illinois; E. S. Gaillard, Kentucky.

Committee on Publications, Drs. F. G. Smith, W. B. Atkinson, D. Murray Cheston, of Pennsylvania; William Lee, District of Columbia; Caspar Wister, Pennsylvania; H. F. Askew, Delaware; Alfred Stillé, Pennsylvania.

Detroit was named for the next annual meeting of the Association.

The report was adopted.

REPORTS OF COMMITTEES.

The following is an abstract of the report of the Committee on

MEDICAL EDUCATION.

"There is much dissatisfaction on the subject of medical education. The administrative agencies are responsible for the failures. In this country education took the typical form some years ago, which still prevails here. That event was in contrast with similar schools in other countries. General education enters largely into the usefulness of medical knowledge. The low rates of tuition are attributable to competition. As education is developed, more remunerative prices will be obtained. We have a right to expect that the schools shall be elevated to the lights of the day. Teachers should give their students every facility for medical advancement. By recognizing the fact that we have the true modes of teaching, it will show that this association is a tribunal before which these questions should be considered." Report referred to Committee on Publication.

MEDICAL LITERATURE.

Dr. Yandell read the following report, submitted by Dr. Flint, who was absent. (We give only a synopsis.)

"The growth of the medical literature of the United States in twenty-five years, since the organization of this Association, must be gratifying to all interested. At the present time we are independent of the world, as regards medical literature. For fulness and clearness, our works will compare favorably with those of our brethren abroad. The rivulet which once constituted our literature is now expanded into a torrent. In this brief report we shall confine ourselves to the productions of our own country. It is profitable to take a survey of these works. No one will deny there are some faults about them, but journalism of a medical character is rapidly improving, and will continue to improve. Several journals have been drawn off, but their places have been more than supplied. They have a vigorous support, and give a wide diffusion of medical knowledge. The redundancy of this literature acts beneficially on our profession; but the complaint is, there are too many medical publications to render them perfect. There should be a less number, and the editors should be well qualified. Like the actor on the stage who is to conduct the snow-storm scene, if his white paper gives out he is compelled to snow brown paper. The contributions are too few, and many of little merit. The editors cannot spare time to revise all these ill-written contributions. They have a right to insist that their communications shall be somewhat correct.

"The department of review has been sadly neglected, and the notices are made up of useless articles.

"The original contributors are desirous of fame, and therefore should seek to let their light shine properly.

"Notwithstanding these necessary defects, our journals are not despised, and many of them are gaining enviable notoriety. Few have betrayed a partisan character. We seldom meet with one that offends against decency. Personalities are eschewed. Much of the improvement must come through the editors. As their profits increase, so will the matter of their publications improve.

"Contributors have much to do with producing this improvement. They should compose their articles with care and earnestness, and write them out clearly and concisely, and practice will make perfect in that as in any other branch.

"The Southern cities entered upon the publication of this style of literature only a few years since, but their improvement has been marked and rapid.

"The fifth edition of Dr. Gross's great work on surgery has been published within the last twelve months, and others have followed in his wake.

"We must close this report. The merits of these works have been widely declared through our medical

journals. The facilities of authorship will increase with the growth of our country, and writers on medicine will spring up all over the country, until there shall be no lack of excellent works."

Referred to Committee on Publication.

COMMITTEE ON PRIZE ESSAYS.

Dr. John S. Moore, Chairman, said, "We have to report the reception of but one essay, and that not worthy of any prize offered by the Association."

COMMITTEE ON PUBLICATION.

The Committee reported "that, after the delay necessary, the twenty-third volume of proceedings, of 1872, was put in the hands of the printers, and we trust it has given satisfaction. These delays were caused by the great amount of written documents, which, as a whole, were ill prepared. We would recommend, therefore, that those submitting documents should prepare them carefully."

Report received, and referred to the Committee on Publication.

TREASURER'S REPORT.

The Treasurer reported that only a small balance remains in the hands of the Treasurer, and, if additional aid is not given, the proceedings of this year's session cannot be published.

Referred to the Committee on Publication.

Dr. J. M. Toner, of Washington, D.C., submitted statistics of hospitals in the United States in 1872–73, derived from replies to inquiries made by the United States Bureau of Education.

A motion was made that these statistics be embodied in the report of annual proceedings.

The Secretary moved their reference to the Committee on Publication, with discretionary power. Adopted.

IN MEMORIAM.

The Secretary then read an obituary letter on the death of Dr. Samuel Henry Dickson, which, on motion, was engrossed on the minutes of the Association for future reference.

Dr. Peck, of Iowa, introduced the following resolution:

"In view of the fact that the reports of the Surgeon-General of the United States Army, as exhibited in volumes one and two of the first part of the Medical and Surgical History of the War of the Rebellion, have received a too limited circulation, by reason of an insufficient issue of the same by Congress; therefore,

"*Resolved*, That the President and Secretary of this Association be directed to petition Congress at the next session in behalf of the profession, asking that the edition recently issued be reproduced in sufficient number to permit of general distribution to the members of the profession throughout the country.

"*Resolved*, That the thanks of this Association are due and are hereby tendered Congress for aiding thus far in developing and presenting to the profession reports of the Surgeon-General, as herein specified.

"*Resolved*, That the thanks of this Association are hereby tendered the officers of the United States Army who have, by sacrifice and labor, been instrumental in placing before the profession the valuable information contained in volumes one and two of the first part of the Medical and Surgical History of the War of the Rebellion."

Carried unanimously.

THIRD DAY.

The Convention was called to order promptly by the President, and at once proceeded to business.

On motion, Dr. Chas. J. O'Hagen was added to the list of foreign delegates.

A letter was received by Dr. John S. Moore from Dr. Paul F. Eve, of Nashville, Tennessee, regretting the necessity for his absence from the Convention.

NOMENCLATURE OF DISEASES.

The Chairman of the Committee on Nomenclature of Diseases submitted the following report:

"In accordance with the resolutions appended to the minority report of the committee, adopted by the Association at its last meeting, one thousand extra copies of the proposed nomenclature were printed in pamphlet form, and distributed to the profession and to the various medical journals, both at home and abroad; and such criticisms and suggestions as would represent their opinions as to its merits and fitness were invited from those receiving it. To this invitation not a single response has been made by medical journals, and but two from practitioners, the latter being such additions as in the judgment of these gentlemen would render the work more complete, but which in the judgment of the majority describe conditions which none but a specialist could recognize. From this statement of the results of a year's consideration of the proposed nomenclature, the conclusion may be drawn that the profession are satisfied with the work. Your committee are not willing to entertain the only other conclusion, that men of culture and practical men are indifferent upon a subject of such importance; they therefore again present the resolution appended to the majority report, and ask for its adoption:

"*Resolved*, That the report of the Committee on the Nomenclature of Diseases be referred to a special committee of five members, to be appointed by the President, who shall examine it and report upon its final disposition, at the present meeting of the Association.

"*Resolved*, That on the favorable report of such committee it shall be referred back to the Committee on the Nomenclature of Diseases, for the preparation of an index to be published with it in the forthcoming volume of the Transactions."

The Secretary moved the adoption of the report.

Dr. Woodward opposed the adoption of the report, and gave in detail his reasons therefor. He then offered the following

RESOLUTIONS:

"*Resolved*, That in the opinion of this Convention it is inexpedient to adopt the nomenclature and classification presented by the majority of the Committee on Nomenclature at the meeting in Philadelphia.

"*Resolved*, That a committee of three be appointed by the President, whose duty it shall be to communicate the foregoing resolution to the proper committee of the Royal College of Physicians of London, and to negotiate for the representation of the American Medical Association in the first decennial revision of their nomenclature."

REPORT OF COMMITTEE ON NOMINATIONS.

The Committee on Nominations, to whom was referred the subject of permanent membership, reported, through their Chairman, Dr. J. B. Johnson, the following names for admission to the Association:

"Edwin Stewart, Mendon, Michigan; G. L. Polk, Æola, Illinois; T. W. Hollowbush, Warsaw, Illinois; John Shore, St. Louis; Wm. Van Zant, St. Louis; Daniel Lichty, Rochelle, Illinois; B. F. Edwards, Kirkwood, Missouri; L. A. Grimes, Lewis county, Missouri; C. W. Crary, St. Louis; L. T. Newman, St. Louis; George F. Center, Olney, Illinois; Drs. R. J. Mitchell,

Lewis Wilcox, R. J. Allmond, W. C. Day, R. T. Cowan, and Edwin Blakesley, all of Illinois; John E. Faber, St. Louis; Dr. Randall, Illinois; Dr. Vinnedge, Lafayette, Indiana; Charles N. F. Ludwig, St. Louis."

On motion, the report was adopted.

Dr. Toner, of the District of Columbia, presented the following resolution in regard to an

INTERNATIONAL MEDICAL CONGRESS.

"*Resolved*, That, in the opinion of this Association, it would be an excellent opportunity, at the American Centennial in 1876, for an International Medical Congress to consider, and, if practicable, to adopt, a uniform classification and nomenclature of diseases, to be used by the profession throughout the world."

The Secretary reported the reception of a letter from Dr. H. R. Storer, which, on motion, was referred to the Committee on Nominations. The letter requested the appointment of a committee to compare the American and foreign winter cures.

REPORT OF COMMITTEE ON ETHICS.

"The Committee on Ethics, of 1872, report in relation to the case of Paluel de Marmon, against whose admission as a delegate to the meeting at Philadelphia, last year, a protest was entered, as follows:

"Dr. De Marmon held credentials as a regular delegate from the Westchester County Medical Society in New York, to the meeting of the Association in 1872. But at that meeting a protest against his admission was made, on the ground that he was on trial for unprofessional conduct in his local society. The subject was referred to this committee at so late a period of the meeting that it could not then be acted upon. From the evidence recently presented to our committee, it appears that the trial of Dr. De Marmon is still unfinished in the Westchester County Medical Society; that said society has formally withdrawn his credentials as delegate to this Association, and consequently no present action in the matter is required by this Association."

Adopted.

REPORT OF PATHOLOGICAL COMMITTEE.

"At a meeting of the Association in Philadelphia, May, 1872, objections were made to the admission of delegates from the Pathological Society of Berks county, Pa., on the ground of non-professional conduct on the part of many of the members of that society. Time not permitting a full hearing of the case during that meeting of the Association, a report on it was postponed until the present meeting of the Association. In the mean time the accused parties were duly notified of the charges, and requested to make answer thereto. After a full investigation of the case, your Committee on Ethics, appointed in 1872, declare a sufficient number of the charges sustained to justify the recommendation that the said society be not allowed a representation in this Association."

Adopted.

COMMITTEE ON SALARIES.

The committee appointed at the last meeting of the Association in regard to the payment of a regular salary to the President and Secretary, made their report upon the resolution then introduced to make the pay of each of the above-named officers $1000 per annum. The committee did not urge the adoption of the resolution as it stood, but left it to the Convention to determine the question.

Dr. Keller, of Louisville, Kentucky, submitted the following resolution as a substitute for the former one:

"*Resolved*, That the sum of $500 be appropriated as an honorarium for the services of the Permanent Secretary during the present year, provided such an amount remains in the treasury after paying necessary expenses."

Adopted.

A NATIONAL SANITARY BUREAU.

Dr. Bell, of Brooklyn, New York, offered the following resolutions:

"*Resolved*, That, in the judgment of this Association, the establishment of a National Sanitary Bureau, with relations to the general government similar to those of the Bureaus of Agriculture and Education, is highly desirable as a means of promoting sanitary science and the protection of the public health.

"*Resolved*, That the Association request of the United States Educational Bureau to so extend the scope of its inquiry as to include vital diseases and mortuary statistics in relation to local, meteorological, and geological influences, and to disseminate the information so collected throughout the country."

The resolutions of Dr. Bell were, on motion, referred to the Committee on State Medicine and Public Hygiene.

Dr. M. A. Pallen offered the following substitute:

"*Resolved*, That Congress be memorialized to create a Sanitary Bureau, and that it be under the control of the Surgeon-General of the United States Army."

Dr. Bell said the resolution of Dr. Pallen would not meet the ends desired. It would have to go through the circumlocution offices at Washington, and it would be years before anything could be accomplished. He was opposed to the substitute, which was lost.

REPORT OF COMMITTEE ON THE CINCHONA-TREE.

"The committee appointed by the American Medical Association to memorialize Congress on the cultivation of the cinchona-tree in the United States, beg leave to present the following report:

"The memorial which was prepared by your committee and endorsed by the Association was duly presented in Congress and referred to the Committee on Agriculture. No further action appears, however, to have been taken upon it.

"Your committee, however, has not been idle, as will be seen by the following facts:

"A committee was appointed by the Medical Society of the State of California, at their annual meeting in 1870, to address the Legislature of California and petition that honorable body to appropriate suitable lands for the purpose. Drs. A. B. Stout and T. M. Logan were the committee selected. These gentlemen prepared a bill, which was introduced near the close of the last session of the Legislature. Owing to the fact that this bill was introduced so late in the session, it was not passed. A very favorable feeling was expressed towards the matter, however, and your committee have no doubt that a similar bill will be introduced and the lands granted.

"In the mean time, the chairman of your committee had opened a correspondence with the Hon. Mr. Watt, Commissioner of Agriculture. Mr. Watt gave assurance of his cordial co-operation in this matter, and has promised to supply whatever seeds may be desired.

"A correspondence has also been carried on between the Commissioner of Agriculture, the State Medical Society of California, and a certain F. A. C. Grebner, who has had fourteen years' experience in the cultivation of this plant in Java, and who is willing to assist in the introduction of the plant into this country.

"In accordance with these facts, a second memorial

has been prepared for presentation to Congress, which is herewith presented.

"Bearing in mind the fact that, although Dr. Royle drew the attention of the British government to the importance of this matter and earnestly urged their action as early as 1839, it was not until twenty years thereafter that the first step was taken in what has proved to be so successful an undertaking as the cultivation of cinchona in India; and, knowing that this matter is already receiving favor here, your committee feel that their efforts have not been entirely useless.

"Your committee would further suggest that, since Dr. Antisell has been appointed upon a commission which will compel his absence from the United States for some years, and will prevent his co-operation with the other members of the committee, the name of Dr. A. B. Stout, of San Francisco, be substituted for his, and that the committee as thus constituted be continued.

"*To the Honorable Senate and House of Representatives of the United States of America:*

"*Whereas*, The American Medical Association, composed of delegates appointed from the State, County, and local Medical Societies throughout the whole United States, constituting therefore the highest medical authority of the country, presented to Congress nearly two years ago a memorial in which they asked Congress for the appointment of a commission of scientific men to determine certain points in connection with the cultivation of the cinchona-tree in the United States; and,

"*Whereas*, Some of these points have already been determined by other experiments in this direction, and the Department of Agriculture is prepared to furnish any needed quantity of the seeds; and,

"*Whereas*, The cultivation of this tree has already been successfully tried on a large scale by the English and the Dutch governments, and the American Medical Association believe that its cultivation by this government would be productive of a very considerable revenue, provided that a proper soil and climatic conditions exist in the United States, which conditions the Committee of the Association are convinced do exist:

"Therefore, The American Medical Association would, through its committee, again respectfully ask the appointment by Congress of a commission of scientific men 'to determine what portion, if any, of the public domain of the United States will produce cinchona, and which may be set apart for the purpose.'

"For the Committee:

"LEMUEL J. DEAL, M.D., Chairman,
"1103 Vine Street, Philadelphia.
"THOMAS M. LOGAN, M.D.,
"Sacramento."

SUGGESTIONS ON MEDICAL EDUCATION.

The hour of eleven having come around, special business was in order, and the report of the special committee was called, to present suggestions on the subject of medical education.

MEDICAL EDUCATION.

Dr. Pollock, of Pittsburg, read the following report:

"The committee appointed by the President, at the last meeting of the Association, to take into consideration the propriety of adopting the suggestions of the Committee on Medical Education, are fully impressed with the importance of the subject, and acknowledge the value of the suggestions offered. But we believe it wholly impracticable to carry into operation any law which does not meet the hearty approval of diverse interests connected with the teaching and practice of medicine; and while we have no doubt that this Association has grown to be a power in the profession, felt and recognized by all, yet to make this power effective its decisions should be calm and deliberate. Therefore, your committee, after due deliberation, have concluded to recommend the adoption of the conclusion of the report of the Committee on Medical Education, which is as follows: That a Congress, composed of two members from each State and Territory, and one from each recognized medical college, all to be members of this Association, be appointed (or nominated by the Nominating Committee) at this present session. That said committee, or congress, shall meet three days previous to our next annual meeting, and that said committee, or congress, shall perfect a plan for some uniform system of medical teaching, which, when adopted by the Association, shall be the only recognized method of medical teaching in the United States."

This report led to a somewhat lengthy and animated discussion. First it was adopted by a close vote; then a motion was made to reconsider the vote, which was done. Then a motion was made to lay it on the table; then that motion was withdrawn.

Dr. Keller, who had seconded the motion to lay it on the table, contended that the gentleman who made the motion had no right to withdraw it without consent of the second. He did not consent, but insisted on the motion to lay the report on the table. The motion was put by the chair and the report laid on the table by the Convention.

Dr. Yandell was opposed to the clause of the report which referred to the election of one from each medical college by the Nominating Committee. With that exception he would be in favor of the adoption of the report.

Dr. Brodie, of Massachusetts, thought there were other objections to the report, and that it was a usurpation of authority.

Dr. Davis thought the gentlemen were out of order, and asked the chair to enforce the rules.

THE CARRIAGE-RIDE.

Dr. M. A. Pallen gave notice of the contemplated trip to Tower Grove (Shaw's Garden) this afternoon, and notified those wishing to participate that carriages would be in waiting in front of the hall from half-past one until two o'clock P.M., at which time they would start.

MARINE HOSPITAL SERVICE.

The amendment to the constitution of the Medical Association, as to its relations with the United States Marine Hospital service, proposed by Dr. Hartshorne, of Philadelphia, at the last annual session of the Association, was brought up and referred to next year's meeting. Its purpose is to place the United States Marine Hospital Service in the same relative position in the American Medical Association as the Medical Departments of the United States Army and Navy.

The following

VOTE OF THANKS

was offered by Dr. Angier:

"*Resolved*, That we hereby tender our sincere thanks to Colonel and Mrs. J. L. D. Morrison for the hospitalities extended to, and so greatly enjoyed by, this Association last evening."

REPORT OF SPECIAL COMMITTEE.

The committee appointed to devise and recommend some plan for securing a more complete report of the doings in the several sections of the Association, respectfully report the following resolutions, and recommend their adoption:

"*Resolved*, 1. That the Committee of Arrangements for each annual meeting of the Association are instructed to secure the services of a sufficient number of stenographic reporters to have one in attendance on the regular sessions of each of the sections in the afternoon as well as during the general morning sessions; that the reports thus obtained be printed the same evening on slips or proof-sheets, in sufficient number to supply all the members of the Association in attendance early the following morning.

"*Resolved*, 2. That the necessary expenses incurred in carrying into effect the foregoing resolution shall be paid from the treasury of the Association in the same manner as other bills relating to the publication of the transactions.

"*Resolved*, 3. That the acting secretary of each section shall keep a file of so much of the reports as may relate to the business of the section to which he belongs, and it shall be his duty to revise the same, carefully eliminating therefrom all that is unimportant, and arranging that which is found valuable and pertinent in proper form; he shall transmit the same to the Permanent Secretary, for the Committee of Publication, within twenty days after the adjournment of each annual session of the Association."

The report was adopted.

Dr. E. L. Howard offered the following

RESOLUTION.

"*Resolved*, That the chairmen of the various sections shall have free scope in the selection of subjects for addresses.

Adopted.

THE COMMITTEE ON ETHICS

reported that the papers necessary to complete the report had not been furnished them until too late for to-day, and they were not ready to report.

The Secretary moved that the next annual meeting of the Association be held on the first Tuesday in June, 1873, at Detroit.

SECTION BUSINESS.

Dr. Davis thought more attention should be paid to the sections, and that strict attention should be paid to their orders of business. There should be a bulletin-board placed upon the stage, designating the day's business; but, despite all he could say, every year there has been blunder after blunder in the sections. The rooms for sections have not been proper ones. Now, at this session, the thing has been greatly improved, and the following are

CHAIRMEN AND SECRETARIES OF SECTIONS FOR 1874.

1. *Practice of Medicine. Materia Medica, and Physiology.*—Dr. N. S. Davis, of Chicago, Chairman; and Dr. Frothingham, of Ann Arbor, Michigan, Secretary.

2. *Obstetrics and Diseases of Women and Children.*—Dr. Theophilus Parvin, of Indianapolis, Chairman; and Dr. Montrose A. Pallen, of St. Louis, Secretary.

3. *Surgery and Anatomy.*—Dr. S. D. Gross, of Philadelphia, Chairman; and Dr. Alonzo Garcilon, of Maine, Secretary.

4. *Medical Jurisprudence, Chemistry, and Psychology.*—Dr. A. N. Talley, of South Carolina, Chairman; and Dr. E. L. Howard, of Maryland, Secretary.

5. *State and Public Hygiene.*—Dr. A. N. Bell, of Brooklyn, Chairman; and Dr. A. B. Stuart, of Winona, Minnesota, Secretary; F. A. Ross, Alabama; D. A. Linthicum, Arkansas; T. M. Logan, California; R. G. Buckingham, Colorado; B. H. Catlin, Connecticut; L. P. Bush, Delaware; F. Howard, District of Columbia; N. F. Westmoreland, Georgia; H. A. Johnson, Illinois; W. H. Myers, Indiana; J. J. Angier, Iowa; D. W. Stormont, Kansas; L. Rodgers, Kentucky; S. Fitch, Maine; James Stewart, Maine; H. J. Bowditch, Massachusetts; R. C. Kedzie, Michigan; A. B. Stuart, Minnesota; J. W. M. Shattuck, Mississippi; John M. Hodgden, Missouri; J. H. Parsons, New Hampshire; E. M. Hunt, New Jersey; A. N. Bell, New York; U. A. B. Norcon, North Carolina; Wm. Clendenin, Ohio; A. M. Pollock, Pennsylvania; G. M. Lenore, Rock Island; R. A. Kinloch, South Carolina; W. K. Briggs, Tennessee; D. R. Wallace, Texas; J. L. Cabell, Virginia; James Bromfield, West Virginia; H. B. Strong, Wisconsin; A. F. Woodward, Vermont; S. M. Bemis, Louisiana.

Resolved, That the Secretary of the Association be authorized to fill up all vacancies in the Committee from the States and Territories.

Also, that Dr. A. N. Bell be President, and Dr. A. B. Stuart Secretary.

COMMITTEE ON NECROLOGY.

Chairman, Dr. A. Sager, Ann Arbor, Michigan, and Committee remain as last year, excepting Dr. Alonzo Garcilon, of Maine, in place of Dr. D. M. Reese, deceased; Dr. W. McCabe, Kansas; J. W. H. Baker, Iowa; J. H. Wheeler, New Hampshire; —— Milligan, Minnesota; W. M. Chambers, Illinois; G. Sutton, Indiana; A. J. Lands, Georgia; B. A. Vaugh, Mississippi; George Mitchell, Ohio; J. J. Woodward, U.S.A.; N. M. Dodson, Wisconsin; L. P. Yandell, Sen., Kentucky.

JUDICIAL COMMITTEE.

Three years.—Dr. Brodie, Michigan; N. S. Davis, Illinois; E. L. Howard, Maryland; Wm. O. Baldwin, Alabama; —— Dean, New York; J. P. Logan, Georgia.

Two years.—L. S. Joynes, Virginia; R. N. Todd, Indiana; —— Askew, Delaware; J. E. Morgan, District of Columbia; Samuel Lilley, New Jersey; S. N. Benham, Pennsylvania; Dr. Dunlap, Connecticut.

One year.—Drs. Bartlett, Wisconsin; Powell, Illinois; Gale, Kentucky; Moses, Missouri; Hughes, Iowa; Bemis, Louisiana; Cheever, Massachusetts.

SPECIAL COMMITTEE.

Dr. H. R. Storer, Boston, Massachusetts, Chairman of Committee to report on American as compared with foreign winter cures.

The report was adopted by the Association *in toto*.

FOURTH DAY.

At half-past nine o'clock, Dr. Logan, President of the Association, called the delegates to order.

PUBLIC HYGIENE.

The Secretary announced that Dr. A. B. Stuart, of Minnesota, resigned the chairmanship of the Section on State Medicine and Public Hygiene, and desired that Dr. Hewett, President of the Minnesota State Board of Health, be appointed in his stead.

Referred to the Committee on Nominations.

RAILROAD ACCIDENTS.

A resolution was passed that Dr. W. F. Peck, of Davenport, Iowa, be appointed a committee to report upon the treatment of injuries from railroad accidents.

PATENT NOSTRUMS, ETC.

Dr. Matchet, of Texas, wanted a committee of three from each State appointed to report at the next annual meeting on the indigenous medical resources of their respective States.

He also offered a resolution in regard to the use of patent medicines and alcohol, which, after brief discussion, was laid on the table.

Dr. Middlekamp, of Warrenton, Mo., proposed the following:

"*Whereas*, The prevalence of the abuse of alcohol has become alarming in the United States, and nine-tenths of the crime committed is owing thereto;

"*Resolved*, That a committee be appointed by the President, of one member from each State, to investigate the effects of intemperance, and report, at the next meeting of the American Medical Association, the proper means to be taken on this subject."

Laid on the table by a decided majority.

AMENDMENT TO THE CONSTITUTION.

Dr. Pollock, of Pennsylvania, proposed the following amendment to the constitution:

"In article VI., line four, the word five be stricken out, and the word ten be inserted, so as to read, 'funds may be obtained by an equal assessment of not more than ten dollars annually on each of the delegates and permanent members,' etc.

"By-laws, article V., strike out the word five and insert the word ten, so as to read, 'the sum of ten dollars shall be assessed annually upon each delegate to the sessions of the Association, as well as upon each of its permanent members.'"

Laid over for one year, under the rules.

DR. HAMMER'S CASE.

The majority of the Committee on Ethics, through Dr. Davis, reported as follows on the protest of the St. Louis Medical Society against the registration of Dr. Adam Hammer, of St. Louis, as a permanent member of the American Medical Association.

"That, after due investigation and the hearing of both parties, it appears that, about one year since, Dr. Adam Hammer was regularly arraigned and tried by the St. Louis Medical Society, of which he was a member, on the charge of violating the code of ethics. After an apparently full investigation, he was declared guilty of the charges, and at a subsequent meeting he was suspended from membership for five years, or until reinstated by a vote of the Society. From this decision of the Society the suspended member appealed to a civil court for legal process to compel the Society to reinstate him. The judge of the court decided that the charter of the Society gave it no authority to take cognizance of any personal assaults or controversies between its members, and issued a peremptory mandamus requiring the Society to rescind its vote suspending Dr. Hammer, and to restore him to his rights of membership. Under this compulsory legal restoration to membership in the St. Louis Medical Society, Dr. Hammer claims the right to be registered as a permanent member at this meeting of the Association. After due consideration, it appears clear to a majority of the members of your committee that the mandamus of the civil court has no other effect than simply to prevent the St. Louis Medical Society from enforcing any penalty against one of its convicted members, and does not in any degree affect the fact that he still stands convicted of having violated an important provision in the code of ethics. The constitution of this Association, in the clause defining who shall be *permanent members*, states 'that permanent members shall consist of all those who have served in the capacity of delegates, and of such other members as may receive the appointment by unanimous vote, and shall continue such so long as they remain in good standing in the body from which they were sent as delegates.'

"Inasmuch as Dr. Hammer still stands convicted of a violation of the code of ethics by the St. Louis Medical Society, and said Society is restrained from inflicting the penalty it has adjudged proper for the offence solely by the interference of a civil court, it cannot be claimed that he now remains in *good standing* in that Society.

"Therefore your committee is of the opinion that Dr. Hammer ought not to be received as a permanent member of this Association at its present meeting."

Signed by Drs. N. S. Davis, H. F. Askew, and D. W. Yandell.

Dr. E. L. Howard made the following minority report:

"The undersigned reluctantly dissents from the report of the majority of the Committee on Ethics in the case of Dr. Hammer, on the following grounds:

"The only question before the committee is, Shall Dr. Hammer be permitted to register as a permanent member?

"The constitution of this Association says, 'The permanent members shall consist of all those who have served in the capacity of delegates, and of such other members as may receive the appointment by unanimous vote, and shall continue such so long as they remain in good standing in the body from which they were sent as delegates, and comply with the requirements of the by-laws of the Association.'

"It appears that Dr. Hammer is still a member of the St. Louis Medical Society, with all the rights and privileges of any other member of that body. The undersigned holds that the committee have no right to examine the case beyond this record.

"*Resolved*, That the name of Dr. Hammer be ordered entered as a permanent member of this Association."

Dr. Hammer maintained that, being accused, he was entitled to a hearing; but he was cut off by the "previous question," when the majority report was adopted by a large vote.

VOTE OF THANKS.

On motion of Dr. Bronson, the following vote of thanks was unanimously passed:

"The American Medical Association, now about to adjourn, would prove derelict in duty and appreciation did it not honor itself by an acknowledgment of the obligation under which it has been placed by the profession, the Committee of Arrangements, the Press, Colonel Morrison, Henry Shaw, Esq., and other citizens of St. Louis, by Dr. Woodward, of the U. S. Army, for the elaborate scientific dissertation delivered last evening under the auspices of the Toner fund, established by Dr. Toner, of the District of Columbia, for initiating a lecture-course of a scientific character; and, last but not least, by the President and other officers of this Association, for the dignified, able, and impartial manner in which they have performed the functions of their offices. Therefore,

"*Resolved*, That the thanks of this Association be extended to each and all of the aforesaid, and that this vote be placed upon our minutes."

Dr. J. A. Alexander, of Virginia, was added to the Committee to represent the United States at the next session of the English Medical Association.

Dr. Frederick Horner, Jr., of Virginia, offered some resolutions condemning the too free medicinal use of alcohol, which were referred to the Committee on Public Hygiene and State Medicine.

FROM THE SECTIONS.

The sections on Surgery, Practice of Medicine, Physiology, Hygiene, etc., reported their minutes and papers, which were referred to the Committee on Publication.

REPORT FROM THE NOMINATING COMMITTEE.

The Nominating Committee made the following report finally:

"The Committee recommend that the nomination of the Committee from the thirteen original States be deferred to the next annual meeting of the Association.

"The Committee request the Convention to reconsider its action in the appointment of Dr. Myers, of Indiana, as a member of the Committee on Hygiene and State Medicine, and that the name of Dr. James F. Hibbard, of Indiana, be substituted.

"The Committee also nominate Dr. W. O. Smith, of Newport, Kentucky, as Chairman of a special committee on puerperal fever."

The report was adopted.

Shortly after eleven o'clock Dr. Logan made his farewell address, and declared the session closed.

[The foregoing report has been arranged with much care from the daily papers of St. Louis.—ED.]

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

A CASE OF CYSTIC KIDNEY WITH IMPACTED CALCULI.

Reported by G. WILDS LINN, M.D., Resident Physician.

MICHAEL W., 75 years of age, was admitted to the hospital March 14, 1873. He then complained of having been ill about two months, saying that he had always been a healthy man previous to that time. When admitted he was tremulous, and complained of chilliness; his lower extremities were much swollen, and purpuric spots were found over the whole surface of the body except the head and face. His urine was found to be opaque, had a reddish-white color, and contained a small quantity of albumen. Microscopic examination revealed a large number of pus-corpuscles with a few red blood-disks and a considerable amount of pigment-matter, but no tube-casts. He complained of no pain; his appetite was good, and he walked about the hospital and to his meals without difficulty. Under treatment the purpuric spots rapidly grew fainter, and the œdema soon disappeared. One week from date of admission his urine had lost its reddish hue, presenting a milky appearance, and on standing gave a heavy white opaque deposit. On examination a small quantity of albumen was found, only sufficient to cover the bottom of the test-tube, and due, probably, entirely to the presence of large numbers of pus-corpuscles, which could still be seen under the microscope. He then grew suddenly much worse, and died on the 27th. I made a post-mortem examination, and on opening the abdomen found a large mass, apparently of fat, fourteen inches long and four inches in diameter, extending from the region of the left kidney and downwards into the pelvis. I removed the mass entire, and upon section found within it a sac, evidently developed from the pelvis of the kidney, ten inches in length and two and a half inches in diameter. Within the sac were five calculi, partly imbedded in its walls, and surrounded by a purulent fluid several ounces in quantity. The largest of the calculi measured four inches in length and one and a half inches in diameter, and weighed four and a half ounces. The next in size measured three inches in length and one and three-quarter inches in diameter, and weighed three and one-fourth ounces. At the upper portion of the mass, where a part of the normal structure of the kidney still remained, was a cyst containing urine, and measuring two and a quarter inches in diameter. The ureter was dilated to nearly three-quarters of an inch in width. The specimens, which were exhibited to the Pathological Society, have been preserved and placed by Dr. Tyson (curator) in the museum of the hospital.

KUMYS IN CHRONIC DIARRHŒA (Prof. Stern, of Vienna: *Wiener Mediz. Presse*, April 13, 1873).—Since the kumys question is fairly afloat, I believe it is the duty of every physician to contribute all in his power which may aid in throwing light on the subject: hence I have been induced to publish the following cases, which I believe contain a certain value:

1. I. K. P., 35 years old, has for four or five years shown a marked tendency towards gout. He has already gone through two attacks of this disease; the first, three and a half years ago, lasted fourteen days; the second, two and a half years ago, lasted five or six weeks. Both attacks were introduced by severe dyspepsia, the pain setting in several days after the dyspeptic symptoms had been relieved. After the first attack a diarrhœa set in, which was very hard to check. The second attack of gout was, however, followed by a still more stubborn diarrhœa. The use of Carlsbad and other systematic "cold-water" treatment so far corrected the arthritic disposition that no fresh attack has occurred. The chronic diarrhœa, however, has remained in all its violence. With care and regulation of the diet, perhaps as much as fourteen days would elapse without any diarrhœa. At the end of this time the trouble would always return with its old violence. As long a period of freedom from the diarrhœa as from two to three weeks could be obtained by drinking constantly red wine and the use of the "cold-water cure." At last even these means lost their power. I then ordered the patient to drink Stahlberg's kumys, at first a small bottle daily, then a large bottle of the strongest variety. In two weeks the patient told me that the kumys agreed with him, that his diarrhœa had ceased, and that his alvine evacuations were regular. He began this treatment in January of this year, and continued it altogether five weeks. There has been no return of the diarrhœa.

The second case is still more important. Mrs. C. S., 30 years old, has been since her childhood subject to repeated attacks of diarrhœa, which often came without any apparent cause. She was obliged to regulate her diet, and to take every precaution to prevent the recurrence of these attacks. Relief was thus obtained for short periods; but at last the attacks increased in number and intensity, until the patient often was compelled to keep her bed.

In December of the year which has just passed, she consulted me, and I advised her last January to try Stahlberg's kumys, in the same way I had ordered it to the previous patient. In this case, too, the effect was surprising. After using the kumys for four or five weeks, the diarrhœa disappeared, and from the 5th of January until now it has never returned.

IDIOPATHIC DIPHTHERITIS IN THE EXTERNAL AUDITORY MEATUS (Moos: *Archiv für Aug- und Ohrenheilkunde*, 1, 2, Abth. 86–88).—Moos observed in a boy ten years old, who had suffered repeatedly from purulent otitis media, a diphtheritic inflammation of the external auditory meatus, characterized by a firm, adherent exudation resembling fat pork (*speckiges*), which remained clinging to the meatus several days, and at last came away, after some pain and hemorrhage. The examination of the throat, the membrana tympani, and the cavity of the tympanum, gave a negative result, so that the diagnosis was rendered in favor of an idiopathic diphtheritic affection, confined to the external meatus.

EDITORIAL.

STATEMENTS WHICH SHOULD BE EXPLAINED.

IN the Philadelphia *Press* of May 19, mention is made of a case of death in the Almshouse Hospital, which became the subject of investigation by the coroner. Some difficulty occurred in regard to the identifying of the body, on which a post-mortem examination had been held; and the reporter makes the following statements:

"What disposition was made of Mrs. McQuaid's remains is unknown, but it is rumored that it is customary after the dissection of vagrant subjects to boil the flesh down in a large cauldron. The bones are then collected, and, as numerous druggists of this city have constant orders on hand for skeletons, it is reported they are sold for that purpose, and that if the subject has a good head of hair, that is neatly stripped off and sold to a fashionable hairdresser.

"This bartering in dead bodies, it is said, has been carried on for a long time, and once caused the discharge of an attaché of the coroner's office. There is a law to the effect that unclaimed bodies shall be distributed among the different respectable colleges, but private physicians offer a large price, and receive nearly all of them."

The writer of the above has sheltered himself behind "it is said," "it is reported," but he knew that there was no foundation for such stories, and he knew also that they would be received by a great many of those who read them, and to whom they were repeated, as implicitly as if they were based upon the affidavits of unimpeachable witnesses. We call upon the *Press* either to withdraw or to prove these statements, which are manifestly injurious to the persons in charge at the Almshouse Hospital, and to the medical profession. If they are true, the sooner the matter is looked into the better.

THE "CREDIT GUIDE."

A FRIEND has expressed to us the opinion that the notice which we gave, in our issue for April 12, to this publication, scarcely did justice to its merits, or rather to its claims upon the profession. He says that he has it in constant use, and that in many instances it has saved him from being imposed upon by those who were willing to employ him but unlikely to pay him.

We are well aware that among the business community there are several publications of a nature analogous to this, and that they are continually referred to for the standing of parties proposing to incur responsibility in the purchase of goods. And we fully believe that the enterprise of those who have issued the "Credit Guide" deserves to be encouraged by the physicians of this city, not only by subscribing for it, but by furnishing correct information for its pages in future editions.

We do not, however, think that the profession will find that the existence of this "black list," even if known to the knavish evaders of bills, will meet the whole of the evil. Let every practitioner have a copy of the Guide, consult it when called to the case of any person unknown to him, and refuse to attend those who figure in its pages. But let him also send out his bills punctually, at short intervals, and give his patients to understand that he means to collect what is due him just as any other business man would. It is in this way that the black catalogue may be lessened, and many an account be saved which would, if not punctually sent out, take its place among our "bad debts."

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.

DEAR SIR,—In your journal of April 5 I find an excellent editorial upon "Some Sins of Druggists." The views therein expressed must meet with the approval of every candid member of our profession. If there be one unpardonable sin on the part of the druggist, we believe it is that of prescribing over his counter. Your definition of his duty is eminently fair and liberal. He has no right to assume prerogatives that do not belong to him. Permit me to cite a few of

the many instances that have fallen under my observation, in proof of this assertion.

Not long since I saw a young man enter a drug-store and address the proprietor as follows: "Doctor, I am suffering with diarrhœa, and wish you to give me something to check it." The druggist asked no questions, but immediately proceeded to put up an astringent mixture, for which he received half a dollar. Now, I maintain that this druggist defrauded a physician out of his fee, and, like yourself in the case you mention, I have endeavored to keep my prescriptions from going to that store.

On another occasion, one of my patients came to my office, in my absence, for a prescription. His case was not an urgent one. As he did not return, I called on him the next day, when he informed me that a certain druggist had prescribed for him, and he was relieved. Do not imagine that many of my prescriptions go to that store.

One day I saw a negress enter a drug-store in this city and ask for *twelve ounces* of laudanum. It was given her and paid for. After she had gone, I asked the druggist how he dared to sell a poison in that way. "Oh," he said, "I know her mistress; she takes it as you would a glass of wine. She will have it; and I might as well make the profit as to let some one else do so."

I have on many occasions heard persons ask a druggist for a good cough or diarrhœa mixture, and he would recommend the Cherry Pectoral, or some cholera nostrum, as the case might be. Now, this is all wrong, and, as you very properly remark, "the business of an apothecary is to sell drugs, either on the prescription of a physician or by the orders received from purchasers." It is not his business to laud this or to condemn that quack preparation. He has no right to compound a prescription unless it is ordered by a regular practitioner. By so doing he practises a fraud upon the profession, and detracts from the real dignity of the healing art.

Again, if a druggist be allowed to rob the physician in this way,—for by prescribing he deprives the physician of the means by which he must live,—should not the physician be permitted to vend his own medicines? And yet he would not be permitted to do so unless he first obtained a license. Such a license the druggist has; but he has no license like that under sanction of which the physician practises,—a diploma acquired by years of patient study, toil, and self-sacrifice.

But there is another sin at the door of the druggists, to which we would briefly refer. A physician gives a prescription in a certain case. It is given for that case alone. It acts well. We have not yet found the druggist who will refuse to renew that prescription as often as desired, if paid for so doing. In our own practice, a prescription was put up more than twenty times and used throughout an entire neighborhood. The druggist acknowledged this fact, and promised to comply with our request not to put it up again unless we should prescribe it. Perhaps he did so.

We are of the opinion that no prescription should be duplicated without the physician's order; and there should be an understanding to this effect between the physician and the druggist, for while the repetition of some prescriptions would be unattended with risk, that of others would be exceedingly hazardous.

Such a rule would not entail hardship upon the poorer classes, for we hold that the fees for professional services should be regulated by the ability of the patient to pay for the same, and those who are really unable to pay should be treated gratuitously.

Between physicians and druggists the most harmonious relations should obtain, for it is to them that the community must look for the means of relief when disease and death hold high carnival in our midst. The responsibility of prescribing is but little higher than that of properly selecting and compounding the remedies prescribed. The prescriber and compounder are coworkers, and they should be actuated by a real sense of the obligations devolving upon them in the discharge of their appropriate duties. One sentiment should ever unite them; it is this: How shall we best work together to promote the welfare of humanity?

Will not the American Medical Association at its next meeting appoint a committee to take this matter in hand and strive to solve the hitherto "unsolved problem"? If so, we believe that great good might be accomplished; that judicious action by such a committee would develop a far better state of feeling between the physician and the druggist than at present prevails.

I am very respectfully, etc.,

H. E. WOODBURY, M.D.

WASHINGTON, D.C., April 16, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR:—I desire, through your columns, to call the attention of the publisher to a number of singular and not very creditable errors which have crept into the American reprint of the "Half-Yearly Abstract of the Medical Sciences" (formerly known as "Ranking's") issued January, 1873. They indicate either a lamentable want of technical knowledge, or excessive carelessness, upon the part of the proof-reader.

In the Table of Contents, Section I., we read, "Art. 8. On Wide Daily Range of Temperature in Connection with *Vegetables* on the *Mitrial* Valves (Rheumatic Disease) and *Separation* of the Spleen." Referring to the article itself, we find "vegetations" substituted for "vegetables," and "mitral" for "mitrial," but "separation of the spleen" is still retained, with no clue whatever to the nature of this singular pathological condition. There is a grotesque completeness about this series of blunders which reminds one rather of a quack advertisement in a daily paper than of a scientific periodical. Dr. Andrews would probably find some difficulty in recognizing his own bantling thus disguised.

On page 58, we have "Art. 44. On the Bending of the Ribs in Forced *Extirpation*."

On page 111, "Art. 106. On Virgin and Humanized Lymph. By Benjamin Lee," contains the following clauses:

"5. That such virus is more likely to induce true *vaccine* in persons already vaccinated," etc., in which *vaccine* is substituted for *vaccinia*; and "6. That what is true of lymph of the first remove is also *immeasurably* true of that of subsequent removes,"—where "*immeasurably*" is substituted for *measurably*, thus completely altering, or rather destroying, the sense of the paragraph. This article, which first appeared in your own journal, is credited to the *New York Medical Journal;* but this is a mistake of the English compiler.

On page 279, in an "Abstract of Lectures on Myology, etc.," by Professor Humphry, F.R.C.S., are found "*rector spinæ*" for *erector spinæ*, in two instances "*cervices*" for *cervicis*, and "*semispinalis*" for *semispinales*.

These instances are taken at random. Similar ones probably exist which a very hasty glance has failed to discover. But alone they are quite sufficient to call for increased care in reproducing the next volume of this standard compilation.

Very respectfully yours,

BENJAMIN LEE.

1503 Spruce Street, May 9, 1873.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, April 23, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

(Concluded from page 526.)

SOME LATE VIEWS CONCERNING THE MODE OF IMPREGNATION.

DR. JOSEPH H. BLATNER remarked that the investigation of the question as to how the semen of the male is brought into contact with the female ovule, or, in other words, the process of conception, involves the consideration of the motive powers which propel the spermatic fluid, as well as of the part which the cervix takes, and, in the many questions which arise, the two are so intimately connected that a separation is impossible. As to how the spermatic fluid is propelled through the cervical canal, opinions vary. The following-named forces have been given: 1st, ejaculation during coition; 2d, peristaltic action of the vaginal canal; 3d, the power of absorption by the uterus; 4th, the piston-like action of the penis; 5th, capillarity; 6th, ciliary motion of the cervical epithelium; 7th, self-movement of spermatozoa.

The peristaltic action of the vagina was observed by Kehrer in animals. This may exist, but cannot act with sufficient force to carry the fluid through the cervical canal. The absorbing power of the uterus, either by peristaltic action or by erection of the organ, has been asserted, but was not considered well proven. Ducilliez and Küss advocated this theory, holding to the view of its being effected by erection of the uterus, —erection causing the formation of a cavity and then producing a vacuum. Objections are that a mechanism of closure of the uterus, like that which is produced in the sucking mouth by means of the pharyngeal muscles, is not in accordance with our knowledge of the uterine muscles; no direct proof has been established either of erection or peristaltic motion of the uterus; no such problematic force is necessary.

The theory that the sperm is thrown directly into the uterine cavity by ejaculation was advocated by Holst, who said that there could be no other reason for the existence of the ejaculation. It is thought, however, that this force is necessary to carry the fluid through the long urinary canal and the vagina: besides, it is observed in animals that deposit it on ready-laid eggs. The meatus urethræ of the male does not coincide with the os externum, as is shown most clearly in the dog. The existence of valve-like or spiral folds in the cervical canal, seen more particularly in the sheep and sow, offers an obstacle that can hardly be overcome by an injected stream. The additional theory that the canal is open during coition, either by erection (Holst) or by reflex muscular action (Vierordt), is opposed by the fact of the close apposition of the walls and the compact structure of the organ.

To prove that the seminal fluid is forced into the uterus by the piston-like action of the penis, it is necessary to show that the vagina is inflexible, has no pocket-like vault, and that it encases the penis so closely that no fluid can escape, so as to allow it no other outlet than the cervical canal, all of which is known not to be the case.

The theory of capillary attraction was entertained by Späth and others. The relatively small cavity and thick walls of the uterus are well adapted to develop capillary force; but the cavity is already filled with a fluid of almost exactly similar consistence as the spermatic.

As to the spermatozoa being carried forward by ciliary motion, the cilia of the cervix and Fallopian tubes move in an opposite direction to that which the former pursue.

Self-movement of the spermatozoa was thought to account for their passage into the uterine cavity, other motor factors being auxiliary. The passage of the spermatic fluid *in toto* into the uterus is not proven, nor is it necessary. Experiments had been made which showed the possibility of the emigration of these cells from their fluid, of their retaining their motive power in different fluids, and that this capacity is affected by the nature of the fluid surrounding them. This migratory action has analogies in other cells.

Direct experiment by Scott on a bitch in heat demonstrated the capacity of these cells to move along the canal unaided. Examinations of animals or man shortly after ejaculation has taken place show spermatozoa only in the vagina or beginning of the cervix. The observation of Sims and others, showing their existence higher up, are not to be considered conclusive. Cases of conception without penetration of the ostium vaginæ by the penis show the possibility of spermatozoa moving from the vulva into the uterus.

That such cases have occurred cannot be doubted. The acid secretion of the vagina is not favorable to their vitality; but this is neutralized near the os by the cervical secretion. The conditions then favoring impregnation are the deposits of semen at the os externum, or, better, in the lower part of the cervical canal, which is possible by the pressure of the penis and the force of ejaculation,—indeed, according to Sims, by the pressure of the cervix against the glans by the contraction of the superior constrictor vaginæ and the dipping of the cervix into the pool of semen in the vagina. Under these circumstances it was believed the spermatozoa could most easily move to their destination.

Drs. DAVIS and DEVOL then remarked upon the subject, after which the Society adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 10, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. S. W. MITCHELL presented a specimen of extensive *exostoses upon the internal surface of the cranium.*

Dr. S. ASHHURST exhibited a specimen of *necrosis of cranial bones in connection with disease of the mastoid cells*, a report of which was published entire in "Hospital Notes" of the *Philadelphia Medical Times* for April 26, 1873.

Dr. J. EWING MEARS presented a specimen of *myxo-sarcoma of the mamma*, removed by Dr. Washington L. Atlee from a patient æt. 55 years. The tumor made its appearance in the left mamma six years since, as a small movable mass about the size of an English walnut. When it was first observed, the patient was suffering from a tumor of the uterus, for the relief of which Dr. Atlee administered muriate of ammonia. The uterine tumor disappeared, and the swelling in the mammary gland slowly increased in size. It was the seat of intense pain at times, especially when a change of weather occurred. Declining to submit to its extirpation, she placed herself under the treatment of empirics who stated that they "could take it out by the roots without the use of the knife." Under this treatment ulceration occurred in December last, and progressed until a very large surface was exposed, which gave rise to a constant and copious serous discharge.

The appearance of the tumor was quite characteristic, —the denuded surface "inflamed and angry-looking," and the subcutaneous veins enlarged and distinctly marked. The glands of the axilla were not involved. In removing the tumor it was found that the pectoralis major muscle had been infiltrated by the disease, and was incorporated in the morbid growth.

On section the tumor showed a number of cysts containing a soft brain-like matter. Microscopical examination disclosed its texture to consist of large round cells in a network of intercellular tissue, and large quantities of small spindle cells, also compound granule cells and free oil granules.

The specimen was referred to the Committee on Morbid Growths, who reported as follows:

"Your committee, having examined the mammary tumor presented by Dr. Mears, have determined it to be a *myxo-sarcoma*. The majority of the nodules of the growth were of a firm consistence, and of a whitish color; a few of the nodules, however, were quite soft, almost gelatinous, and semi-transparent. In the latter were found true mucoid tissue, with stellate cells; whilst in the denser portions of the growth the connective-tissue elements predominated, composed of two varieties of cells, one small and spindle-shaped, the other round and nucleated. The intercellular substance is of hyaline, structureless appearance."

Dr. DE FORREST WILLARD presented a pair of *large smooth white kidneys*. The patient, a man 26 years of age, had never been in robust health, but had been able to continue at his work until four months previous to death. He did not come under observation until mental hebetude was so marked that no satisfactory history could be obtained. Two months before his death, he had convulsions for several weeks. There was troublesome cough for the last month of life; no hæmoptysis. The urine contained a very large amount of albumen,—nearly three-quarters. Death occurred from exhaustion, without convulsions.

Autopsy.—Kidneys both greatly enlarged,—7 inches in length, 4 inches in breadth, and 2½ inches in thickness. Cortical substance thickened, and exceedingly fatty, its color being almost white, and presenting a marked contrast to the dark congested pyramids. The pelvis and ureters were normal. There was a large cavity in the apex of the left lung, and several smaller ones in the upper lobe; the entire remainder of the upper lobe, and a portion of the lower, were studded with tubercles. The right lung was nearly in the same condition, the cavity at apex, however, being smaller.

The other organs presented no marked pathological changes.

Dr. JAMES TYSON presented a case of *cystic kidney with impacted calculi*, which is reported by G. Wilds Linn, M.D., in another column of the *Medical Times*.

GLEANINGS FROM OUR EXCHANGES.

RESINA COPAIBÆ AS A DIURETIC (*Lancet*, March 22, 1873).—Dr. Wilks speaks with the greatest confidence of the value of the resin of copaiba as a diuretic. The ordinary copaiba has long been known for its action on the kidney, and is occasionally used in dropsy, but the nauseous taste of the oleo-resin has almost forbidden its employment. The oil separated from the resin is officinal, and is often prescribed in gonorrhœa instead of the compound substance. It is thought that the oil acts more especially on the mucous membranes, and is therefore useful in affections of the bronchial, vesical, and urethral surfaces. If this be so, it is equally certain that the diuretic properties reside in the resin. Dr. Wilks has found it very difficult for patients to take the ordinary pharmacopœial drug, and almost impossible to get general practitioners to sanction its administration in private practice: he therefore has substituted for it the simple resin, and finds it equally or more efficacious. He gives fifteen or twenty grains in mucilage and flavored water three or four times a day, and has had numerous cases showing its marked diuretic properties. There was in Guy's Hospital a man who came in with ascites, and who, after taking numerous other remedies, was ordered the resin. The amount of urine was at once doubled in quantity, and after a few days the fluid almost entirely disappeared. Dr. Wilks states he has lately had as a private patient a "drunkard builder," for whom he likewise prescribed the resin; a diuretic action was at once effected, and the dropsy quickly disappeared. In heart-cases also he has given it with great success. Lately there was in the hospital a girl with mitral disease and considerable dropsy, who took the usual medicines without effect, and was then ordered the copaiba. It at once produced the desired effect, and the fluid was dispersed. Dr. Wilks says he has often given the remedy and failed; but, on the other hand, when it has succeeded, the result has been more striking than with any other diuretic he has seen. He would desire to see it introduced into the Pharmacopœia, as it is not kept by chemists, although he is informed it is used largely by perfumers, and the resin thrown away in large quantities as a waste material.

TREATMENT OF CEREBRAL EXHAUSTION (*British Medical Journal*, April 11, 1873).—In his Croonian Lectures, lately delivered, Dr. Radcliffe, after describing the principal symptoms of cerebral exhaustion as failure of memory, depression of spirits, increased or diminished sleepiness, unusual irritability, a continued craving for food or for stimulating drinks, lessened locomotive power, lessened control over the bladder, diminished sexual activity, inequalities of circulation, an aged aspect, disposition to tears, yawning, occasional faintness, epileptiform symptoms, or transitory hemiplegia or coma, proceeds to consider its prevention and treatment. In diet, he

thinks that the present system of urging persons at all weakly, especially children, to eat as much as they can, may have not a little to do in causing the development of many nervous diseases. He is equally opposed to persistence in "training diet" and to Bantingism, believing that the nerve-tissues as well as others may be effectually starved by excluding the hydro-carbons from the food. He further thinks that too much stress is ordinarily laid upon the importance of walking exercise; much walking, in fact, seeming to be no insignificant cause of the break-down in the patient's health, and little or no progress is made until he begins to economize his strength in this direction. He is also disposed to maintain that rest from head-work may be too much insisted upon in cerebral exhaustion. He is satisfied he has often met with patients with jaded brains who have certainly let their minds lie fallow too long. Mere distraction is not enough. What is wanted generally, even at the beginning, is not that work should be given up altogether even for a short time, but that it should be moderated in amount, or changed. He is of opinion that the wakefulness may be much better combated by attention to the position of the head in sleep than by narcotics. Sleep in bed is, as a rule, sounder with a low pillow than with a high one. On the contrary, if there be undue sleepiness the head should be kept high.

Perforating Idiopathic Ulcer of the Œsophagus (*Irish Hospital Gazette*, February 15, 1873).—Dr. J. Hawtrey Benson exhibited to the Pathological Society of Dublin, February 1, a morbid specimen and illustrative colored drawing of the above rare affection. The case was that of a woman, aged 50, but with the appearance of a person of 75 or 80, who looked as if she was a sufferer from cancer, especially as the glands in the groin, neck, axillæ, and mesentery were enlarged. She complained of soreness, referred to the centre of the sternum, and of extreme dysphagia. From these circumstances, cancer of the œsophagus was diagnosed, and she was nourished by the rectum for three weeks, when, one morning, she said she could swallow with perfect ease. A diagnosis of a tumor pressing on the œsophagus, which, from some unknown cause, had shifted its position, was now made. After the favorable change in the symptoms had continued for ten days, uncontrollable diarrhœa set in, from which she died. At the post-mortem examination, an oval-shaped ulcer, about the size of a shilling, was found to have perforated the œsophagus about five inches above its cardiac extremity; the pleura adjacent to the ulcer had been attacked, as shown by a patch of vascularity, but there was no extravasation of food during life. There was a ragged ulceration in the œsophagus surrounding the perforation; and in connection with this portion of the tube was a tumor, about the size of a hen's egg, which, however, was not of a cancerous nature, but mainly composed of gland-tissue. Dr. Benson, in explanation of the symptoms, thought that the dysphagia depended on spasm from the passage of food, which ceased to occur when the disease extended more deeply into the tissues. The specimen was a very rare one. The writings of Hamburger and Oppolzer had thrown some light on the obscure nature of the diseases of the œsophagus, about which previously but little was known.

Acute Purpura in a Child Two Days Old.—Dr. F. W. Campbell, in the Canada *Medical Record*, March, 1873, reports a well-marked case of purpura in an infant two days old. There was nothing abnormal noticed about either mother or child at the time of birth. For two days the child was active, and apparently well. Then it began to bleed from the nose, gums, ears, and bowels. The skin was of a dusky hue, and covered with small petechial spots. In spite of all treatment, the child sank, and died in twenty-four hours, evidently from exhaustion.

MISCELLANY.

A Vienna "Rigorosum."—Dr. D. Inglis, writing from Vienna to *The Detroit Review of Medicine and Pharmacy*, thus describes a scene at a *rigorosum*, or examination:

"At last, a woman was brought in from the adjoining lying-in room, who had been in labor forty-three hours, membranes ruptured thirty-three hours previously, uterine contractions almost continual, and everything indicating the use of the forceps, head high in the pelvis, occiput towards the left. One of the students having made this diagnosis, the forceps were called for, the next student in order applied one blade, the next the second, the third locked them, and the next three took turns in making traction, but, being unable to accomplish any advance of the head, the professor himself took the forceps, and was likewise unsuccessful.

"He then asked what was to be done next, and, on being answered, 'craniotomy,' the curved trephine and Braun's cranioclast were brought out, and, much to our astonishment, one of the students was requested to apply the trephine, while a second assisted.

"The head being successfully perforated, a couple more students, after some devastation among the assistants' shirt-bosoms, caused by an excited and inaccurate use of the syringe, succeeded in washing out the brain-substance.

"It being now well past supper-time, we adjourned for an hour, to allow the uterus, if possible, to finish the labor without further instrumental assistance; when, no uterine contractions having taken place during the interval, the cranioclast was produced. The gentlemen under examination now alternated in applying this instrument and forcibly tearing out small portions of the child's skull, until at length Prof. B. concluded that the *examination* had proceeded far enough, and attempted to extract with the cranioclast; but, the parts being by this time so much lacerated, he was unable to do so, and only by using a cephalotribe was he at last enabled to end the scene. Such was the first obstetrical rigorosum of the term; and it well deserved the name."

Stevens Triennial Prize.—The Stevens Triennial Prize for 1873 has been awarded to an Essay on "The Sphygmograph: its Physiological and Pathological Indications," by Edgar Holden, M.D., of Newark, New Jersey.

The questions proposed for the next prize (1876) are as follows:

I. "The History of Epidemic Diseases in the United States, from 1860 to 1870;" statements as to localities, dates, extent of prevalence, and mortality, to be au-

thenticated by appropriate references. The question of *treatment* is not to form a part of the above subject.

II. "The Use of the Spectroscope, in its Application to Scientific and Practical Medicine."

The competing essays on either of the above subjects must be sent in to the President of the College of Physicians and Surgeons, New York, on or before the first day of January, 1876. Each essay must be designated by a device or motto, and must be accompanied by a sealed envelope, bearing the same device or motto, and containing the name and address of the author. The envelope belonging to the successful essay will be opened, and the name of the author announced, at the Annual Commencement of the College, in March, 1876.

This prize, which will amount to two hundred dollars, is open for universal competition.

By order of the Prize Committee,

J. C. DALTON, M.D.

DIFFERENCE OF LONGITUDE.—"We are sorry," says the London *Medical Times and Gazette*, "to observe that the medical officer of St. George's-in-the-East Workhouse, against the unanimous wish of the Guardians, is strenuously opposing what is in most workhouses a customary allowance of beer for paupers who work as tailors, shoemakers, etc., thus partially recouping the parish for their keep. It is difficult to conceive what valid objection the doctor can have against the very moderate allowance of beer customary in such cases. However, as the Poor-Law Orders require the sanction of the medical officer to the bestowal of malt liquors, we suppose the working inmates will be deprived of their harmless luxury."

Paupers in this country are not accustomed, except by special orders of the physician, to such "harmless luxuries."

SUIT FOR MALPRACTICE.—We see it stated in the daily papers that a suit for $10,000 damages has been brought against Dr. J. D. Schooley, of Braddock borough, Alleghany County, Pa., for malpractice in the case of a man named Hodder, by bandaging an injured limb so tightly as to cause mortification and death. The plaintiffs are the widow and her four children.

THE *Obstetrical Journal of Great Britain and Ireland* is to be republished in this country by Mr. H. C. Lea, with a supplement of sixteen pages, edited by Dr. William F. Jenks, of this city. The first number has appeared, and is in every way creditable.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 13, 1873, TO MAY 19, 1873, INCLUSIVE.

IRWIN, B. J. D., SURGEON.—Granted leave of absence for twenty days. S. O. 72, Department of the Missouri, May 14, 1873.

PHILLIPS, H. J., ASSISTANT-SURGEON.—To report in person for duty to the commanding officer of the Modoc Expedition. S. O. 51, Department of the Columbia, May 2, 1873.

HEIZMANN, C. L., ASSISTANT-SURGEON.—Assigned to duty with the expedition for the reconnoissance of Northwestern Wyoming. S. O. 80, Department of the Platte, May 15, 1873.

EWEN, C., ASSISTANT-SURGEON.—Granted leave of absence for thirty days. S. O. 78, Department of the Platte, May 12, 1873.

ORIGINAL COMMUNICATIONS.

TWO CASES OF PURPURA RHEUMATICA.

BY LOUIS A. DUHRING, M.D.,

Clinical Lecturer upon Diseases of the Skin in the University of Pennsylvania, and Physician to the Dispensary for Skin Diseases, Philadelphia.

INASMUCH as the following cases are interesting examples of the process or disease known as purpura rheumatica, and at the same time offer certain peculiarities which are of value in a diagnostic point of view, I take the opportunity of presenting them. The cases are quite similar, and, as so often happens with rare or odd forms of disease, they both came under my notice at the same time, about six months ago. Purpura rheumatica, or peliosis rheumatica, as it was originally called, one of the three varieties of purpura, is a disease of uncommon occurrence, and possesses a curious array of symptoms, all of which are usually found accompanying the disorder. At times, however, it happens that some of these signs are but imperfectly exhibited, and that the cutaneous manifestation of the disease offers odd and varied appearances. Moreover, the diagnosis of the affection, though sufficiently easy when the case is typical, may at times be difficult; especially so when the eruption is only partially developed and the true nature of the anatomical lesion almost imperceptible. Such was the condition in both of the instances about to be detailed at the time when I first saw them.

The first case is that of Anna K., a young American girl, single, twenty-two years of age, and a domestic by occupation. She came under my notice in September, 1872. Her health had been excellent until three months previous, when she began to get thin and pale, frequently complaining of weariness on slight exertion, with pain in the back, constipation, and loss of appetite. These symptoms continued to about the same extent for two months, when they suddenly became aggravated. Headache, together with a sense of unusual heaviness of the head, was now almost constant. For a week preceding the eruption she experienced severe pains in the arms, extending from the elbows to the finger-ends. The legs as far down as the ankles were also affected in the same manner, but the body was not involved. The pain was of a dull, aching character, which came upon her at dark and continued through the night. The fingers now became swollen, stiff, and painful, while the general symptoms of distress were very great. At about this time the eruption made its appearance suddenly, while she was attempting some manual labor. It first showed itself over the arms and backs of the hands, in the form of small, reddish spots, many of which were raised above the level of the skin. The elevation referred to lasted through the day, but by the next morning had greatly subsided. Two days after this the eruption appeared upon the legs and backs of the feet, and a few days later upon the trunk. With the first sign of the breaking out the pains, which had been so severe, left her almost entirely. On September 17, the occasion of my first visit to the patient, I found her very pale in color, without appetite, bowels very much constipated, flatulent, weak, very low-spirited and despondent. She had a constant craving for long-continued sleep, and could scarcely resist the temptation of sleeping through the entire day. After the appearance of the eruption the skin of the arms and legs became very sensitive, the slightest knock or bruise causing great pain. With the outbreak of the skin manifestation her catamenia came upon her, out of regular time, and flowed almost uninterruptedly, with great loss of blood, for two weeks. Upon examining the skin I found numerous faint, reddish spots well scattered over the arms, legs, thighs, and abdomen. I make use of the indefinite word spot because at first sight it was difficult to determine what the elementary lesion actually was. Some were slightly raised in the form of papules, but the greater number were upon a level with or beneath the surrounding skin. They were roundish or irregular in outline, and varied in size from a pin's head to a pea. Many of them possessed no marked line of contour, but appeared to fade away imperceptibly into the healthy skin. Again, in other places the eruption seemed to be strictly macular, with no visible sign of hemorrhage into the tissue. In general appearance it bore a great resemblance to a fading syphilitic erythema. Close inspection, however, revealed the anatomical lesion to be a cutaneous hemorrhage, though very slight and superficial in character. It must not be forgotten in considering these unusual signs of purpura that the eruption was not in its first stage, but had existed some ten days. Rest, good food, and a preparation of iron and cinchona were directed for the patient. A week later found her condition decidedly better; the catamenia had ceased, the skin was no longer sensitive, the pains had disappeared, and there was no appearance of new hemorrhage visible. This improvement continued for a month, when one day, after the violent exercise of washing clothes, an eruption of small, red, elevated spots appeared over the arms, attended with marked swelling, heat, and itching. This remained visible for a day or two only, and disappeared without trace. The following week, while washing, this same trouble again manifested itself. She at once visited me, for the purpose of allowing me to see the eruption in its acute stage. It proved to be a well-marked multiform congestive erythema, which lasted but a day or two. There was no hemorrhage. After this the patient had no further trouble, but continued to improve rapidly. I may mention that I have quite recently seen her, and that she considers herself as entirely recovered. A mottled staining of the skin is still visible about the limbs, the only trace of the former affection.

During the latter part of last summer I was requested to see Mrs. A., a married lady, about thirty-five years of age. She was the mother of four children, the youngest of which, twenty months old, she was still nursing. She informed me that

she had been in poor health for some months, but that within the last few weeks she had been without appetite, and that her strength had failed her. She said that she had also experienced dragging pains throughout her body and limbs, and that an extensive eruption had made its appearance over her body. This eruption had come out very rapidly, and had occupied the entire body in the course of two or three days. It first made its appearance in the form of small, round elevations, which had a resemblance to nettle-rash. Since the breaking out the whole skin had been very sensitive and sore, the slightest knock giving great pain.

Upon examining the lady, I found her exceedingly prostrated, scarcely able to walk about the room. She was very low-spirited, nervous, and singularly despondent, making the assertion to me that she knew she would never recover. Her complexion was pale, and the skin generally was loose and flabby, and very painful if touched or handled. A copious eruption existed over the limbs and body, which consisted of small, pin-head to pea-sized, roundish spots, situated apparently in the corium. Most of them were ill defined, with little or no line of demarcation about them. Some were raised in the form of papules, while others less distinct were beneath the level of the skin. Some of them were also macular, and appeared quite superficial. The color varied very greatly, according to the locality and the duration of existence. Some were pinkish, while others had a faint, dirty-reddish hue. The eruption existed generally over the whole skin, though it was more pronounced about the back and abdomen. There was no tendency to grouping, nor was there any itching present. Careful examination determined the eruption to be due to minute hemorrhages into the skin. But this diagnosis was by no means easily arrived at, for the lesion bore a close resemblance to the skin manifestation of early syphilis. It looked exceedingly like the stage of dermato-syphilis which is so commonly seen, where the macular and papular forms seem to join each other imperceptibly. The hemorrhagic nature of the disease was only recognizable after the closest scrutiny. The eruption resembled syphilis much more than it did purpura as we usually see it; and it is this similarity to the former trouble which makes the present case so interesting in a diagnostic point of view. The history in most cases of purpura rheumatica, together with the usually marked hemorrhage into the skin, leaves no room for doubt as to diagnosis; yet, when no authentic history can be obtained, or where we rely upon the objective symptoms for diagnosis, an irregular form of eruption such as occurred in the present case may readily lead one astray.

With reference to the treatment of the patient, I would say that the child which she was nursing was directed to be weaned at once. Good diet, beef-soup, ale, and a preparation of iron and phosphoric acid with bark were ordered, and the assurance given to the patient that she would undoubtedly recover her former good health. Unfortunately, I was not able to see this case again, nor could I obtain exact notes of the subsequent changes in her condition; but I have recently heard that the skin-trouble left very slowly, and that improvement in her general health progressed likewise at a tedious pace. However, to what extent my directions were followed, or whether they were instituted at all, I am unable to state, my impression being that no regular course of treatment was insisted upon either at that time or since.

NOTES OF HOSPITAL PRACTICE.

WILLS OPHTHALMIC HOSPITAL.

SERVICE OF GEORGE C. HARLAN, M.D.

Reported by W. H. Winslow, M.D.

TRAUMATIC OPHTHALMIA.

J. P., a farm-hand, æt. 28 years, was picking frozen earth, when a piece struck him in the left eye and produced contusions, resulting in a sloughing ulcer. He presented himself for treatment one week after the occurrence of the injury. There was much pain, the conjunctival and deeper vessels were injected, and an onyx formed at the lower margin of the cornea. He was admitted to the hospital, blood taken from the temple by the artificial leech, a solution of sulphate of atropia instilled often, and a borax and camphor wash applied several times during the day. In a week the ulcer had nearly filled up, and the general symptoms were much improved, though some conjunctival redness remained. The treatment was continued, with the addition of a gr. iv solution of nitrate of silver applied to the inner surface of the lids twice daily. The patient went rapidly on to recovery, and was discharged cured on the twentieth day.

CORNEO-SCLEROTIC TUMOR.

C. H., a man æt. 60 years, was at the hospital one year ago with a white warty growth upon the conjunctiva, overlying the corneo-sclerotic border of the left eye; it was removed by scissors and caustic. He returned with a recurrence of a similar irregular, yellowish-white structure, resembling myxoma, in the same situation as before; extending along the corneal rim upon the outer side about three-eighths of an inch downwards, two lines in width, and raised above the surface of the conjunctiva about a line.

It was thoroughly removed with scissors, the edges and surface touched with a point of nitrate of silver, which was neutralized by a solution of common salt before the lids were allowed to close, and a borax and camphor wash ordered to be applied frequently.

The caustic was applied twice subsequently, and the patient was well at the end of one week, and discharged.

IRITIS.

F. M., a man æt. 29 years, a conductor by occupation, confessed to having had chancre last January, followed by specific eruption and sore throat, from which he recovered under regular treatment.

Three weeks before his appearance at the clinic, he suffered from congestion and pain in the right eye, which remitted somewhat after a few days, without treatment. He complained of tinnitus aurium, and had pharyngeal catarrh with granular condition of the mucous membrane. There was tenderness along the tibial spines, and pain with nocturnal exacerbations. Both eyes were found injected, with episcleral zones well marked, and in the right much photophobia and orbital pain. Vision in the left was normal, but in the

right it was only $\frac{20}{\overline{LX}}$ of Snellen. The pupils were sluggish, and instillation of atropia showed an annular synechia, unyielding in the right, but the left gradually and irregularly dilated, there being only a few points of attachment.

He was ordered pot. iod., gr. x, three times a day, mercurial inunction at night, and atropia wash. The iritic attachments yielded rapidly in the left eye, but the annular synechia remained in the right until the system came well under the mercurial influence, when the repeated instillation of atropia, gr. viii to ℥j of water, in two hours tore away the attachments, leaving small particles of uvea upon the anterior capsule, and the pupil widely dilated.

The mercury was suspended, and the iodide continued with the atropia wash; he made a rapid recovery, and was discharged the twenty-first day, with vision normal and eyes perfect.

T. P. F., a healthy-looking man, æt. 28 years, a laborer in a foundry; complained of pain and a watery condition of the right eye.

He said he had never had syphilis or rheumatism, but had had gonorrhœa several months previously to his appearance for treatment. The left eye was normal; the right was injected and irritable, with much orbital pain, and he had slight constitutional fever. The pupil was sluggish, and there were several attachments to the anterior capsule. Vision equalled $\frac{20}{\overline{LXXX}}$ Snellen. A solution of atropia, gr. iv to f℥j of water, was ordered to be instilled three times a day, the eye to be bathed frequently with a borax and camphor wash; f℥jss of blood to be taken from the temple immediately by leeches, and pot. iod., gr. x, with hydrarg. corros. chl., gr. $\frac{1}{12}$, to be taken three times a day.

He was somewhat better the third day, and the pupil was well dilated; but leeching was ordered again, and the atropia and alterative treatment continued.

He improved rapidly until the seventeenth day, when, after exposure to wind and cold, he returned with renewed pain, increased episcleral zone, cloudiness of the aqueous humor, and dulness of the cornea.

He was given gr. ⅛ morph. sulph., and f℥ss ol. terebinth., three times daily, and the alteratives were discontinued. As this produced strangury, the morphia was omitted, and gtt. x tr. opii were taken with each dose. Four days after this his eye had much improved, vision had risen to $\frac{20}{\overline{XL}}$ Snellen, and he seemed to be getting along finely. The turpentine and laudanum were discontinued, and alterative treatment again directed. One week afterwards there were few symptoms of importance remaining; but upon testing his vision it was found only $\frac{20}{\overline{LX}}$ Snellen. Ophthalmoscopic examination revealed a cloudiness of the vitreous with movable shreds of lymph, and the deeper structures could not be well discerned.

J. S., an intemperate man, æt. 45 years, a tavern-keeper, had syphilis fourteen years ago, but he denied having had any appearance of it since. His wife and children enjoyed good health.

Upon examination, superficial keratitis was found in the right eye, with iritis and an annular synechia. Vision in the left eye was normal, but in the right was only $\frac{2}{C}$ Snellen. He was ordered gr. iv pil. hydrarg. twice a day, a wash of gr. ii atrop. sulph. to ℥j aquæ destil., and ℥j of blood to be taken from the right temple by leeches. In two days the iritic adhesions had all yielded, except one at the lower and inner side, the remainder of the pupil being widely dilated.

The fourth day he was well under the mercurial influence, the pupil was regularly dilated, and the inflammation and pain were much diminished. The blue pill was now stopped, and pot. iod., gr. v, with hydrarg. chlor. corr., gr. $\frac{1}{16}$, ordered to be taken three times daily, and the atropia wash continued.

In two weeks vision was normal, and he had entirely recovered.

RETINITIS.

T. N., æt. 51 years, a machinist by occupation, but formerly a soldier of the French army in a detachment stationed at Algiers. First wore glasses at the age of twenty-seven years. His health was and had generally been good, and he denied positively having ever had venereal disease, but occasionally suffered from slight rheumatic pains. He applied for relief on account of a dimness of sight, which he noticed first about four months previously, and which had increased steadily. The eyes externally appeared healthy. Vision in each eye was $\frac{14}{C}$ Snellen; Hypermetropia = $\frac{1}{7}$.

Ophthalmoscopic examination of the right eye showed media clear, and little grayish spots, the size of a millet-seed, scattered in the fundus at the outer side of the disk and around the macula; there were white streaks along some of the larger vessels, the retinal circulation was excessive, and the disk doubtful. In the left pretty much the same condition prevailed, but the spots were rather more abundant, and there was a slight bluish haze about the edge of the papilla. These spots were irregular in shape, like little pearly grains in the retina, somewhat resembling those found in Bright's disease; but repeated examinations failed to detect any albumen in the urine.

He was ordered gr. $\frac{1}{24}$ hydrarg. chlor. corr., and gr. v iodide of potassium, three times daily, and kept under observation. The chloride was discontinued after a few weeks, and the iodide given alone. In three months vision had risen to $\frac{20}{\overline{XL}}$ Snellen in the right eye, and to $\frac{20}{4}$ in the left. As he suffered from constipation, he was ordered a pill of aloes, colocynth, and belladonna, to be taken every night. At the end of the fourth month most of the spots in the fundi had disappeared, vision had risen to $\frac{20}{\overline{XXX}}$, and, as improvement seemed to have stopped, he was ordered spectacles of $+\frac{1}{7}$ to neutralize his hypermetropia, and dismissed with instruction to return occasionally for examination.

E. R. T., a woman in robust health, æt. 19 years, came to the clinic February 1, complaining of a dimness of sight, which had come on suddenly one evening, and the next day she had found herself unable to read ordinary print. She had an offensive nasal catarrh, and her hair had fallen out slightly some months before; but no other symptom of a syphilitic taint could be discovered.

She stated that she had pursued her occupation of machine-sewing, without serious difficulty, until a few days before the sudden failure of vision. Externally the eyes were healthy. Ophthalmoscopic examination of the left eye showed a high degree of myopic astigmatism, and an extensive staphyloma posticum, but a fundus otherwise normal. A $-\frac{1}{5}$ spherical combined with a $-\frac{1}{12}$ cylindrical at 30° gave a vision of $\frac{20}{\overline{XL}}$ Snellen in this eye; but without the glass there was no useful vision, and she had evidently depended entirely upon the other eye.

In the right eye there was a peculiar irregular grayish-white cloud-like patch, extending downwards and outwards from the disk, about three disk-diameters in width and six in length; several interrupted retinal vessels passed over it, and there were numerous hemorrhagic extravasations upon its surface. Vision in this eye was $\frac{20}{\overline{LXXX}}$ Snellen with a $-\frac{1}{10}$ glass. The bowels were constipated, and she was ordered a purgative, sent to bed, blood taken from the temple by the arti-

ficial leech, and hydr. chlor. corr. and iodide of potassium given in alterative doses.

February 3.—A slight decrease of the patch was noticed at its lower edge, which had become ill defined, the healthy fundus, as it were, encroaching upon it. The leeching was repeated and alteratives continued.

February 5.—The fundus was rapidly assuming its normal characteristics at the lower part of the patch, giving the upper edge, by contrast, the appearance of a silvered cloud. Leeching was repeated, and other treatment continued, with the addition of a Seidlitz powder every morning to relieve constipation.

February 24.—There was nothing left of the exudation except a narrow cloudy streak, corresponding to what had been its upper margin, extending outwards and downwards from the disk, which might almost have escaped notice if its locality had not been previously determined. She stated that "her sight was as good as it ever had been," and it was found that she could read $\frac{20}{XXX}$ Snellen with some difficulty.

March 14.—Very little change had occurred, either in ophthalmoscopic appearances or vision. She was directed to take iodide of potassium, gr. x, three times daily, and discharged at her own request.

The Progress of Syphilis during Pregnancy (by Prof. Sigismund, of Vienna: *Le Mouvement Médical*, April 26, 1873; from *Wiener Mediz. Presse*, 1873).—In this clinical lecture the author confines his remarks to syphilis contracted by the genital parts either during or just before pregnancy.

The liability to contract syphilis is greater among women who are pregnant than among those who are not, and for the following reason: The inoculation of the virus is singularly favored by a kind of catarrhal condition of the mucous membrane lining the genital parts, by the presence of a blennorrhea, and by the presence of erosions of the labia and of the vaginal portion of the cervix. These erosions of the neck are due to a true maceration in the alkaline cervical mucus. The duration of the period of incubation of syphilis is the same during pregnancy as in the normal condition. The onset of syphilis is not often recognized by pregnant women, the primary manifestations being ascribed by them to the pregnancy itself; midwives frequently make the same mistake.

The primary manifestations of syphilis always develop in the same locality whether the woman is pregnant or not, but they are in the former case more obstinate, more rapid in their progress, and have a greater tendency to spread.

Relapses occur frequently. Diffuse redness of the skin, superficial excoriations, disseminated or agglomerated follicular abscesses, herpes, eczema, œdema of the genital parts or of the anal region, are of frequent occurrence during pregnancy. To these different lesions must be attributed not only the easy inoculation of the syphilitic virus, but also its markedly rapid extension in pregnant women. In addition to the preceding causes, the maceration of the skin by the contact of various irritating fluids—perspiration, sebaceous matter, urine, mucus, and muco-pus—explains how the neighboring lymphatic ganglia may become rapidly infected. Syphilitic indurations or papules involving either the vaginal portion of the cervix or the fourchette may prove very dangerous at the time of the labor. In fact, the tissues swollen or infiltrated by syphilitic exudations lose their elasticity, become inextensible, and tear easily during the passage of the fœtus. The resulting wounds have a tendency to slough, and may bring about an inflammation of the neighboring chain of lymphatics, or may even give rise to pyæmia. This is especially true of wounds of the vaginal portion of the cervix uteri.

The secondary syphilitic manifestations are, on the contrary, of a relatively benign nature. They are feebly pronounced on the skin and mucous membranes; falling of the hair, visceral affections, and "syphilitic fever" are seldom observed during pregnancy. The same is true of disease of the nervous system (syphilitic pains, convulsions, etc.), and, in general, of all the grave forms of secondary syphilis. The author explains this fact by the changes going on in the economy of the pregnant woman; the blood becomes less rich, the activity of the different functions becomes greater; the secretions, and especially that of the mammary glands, are increased. If this last explanation be accepted, it is important in the treatment of syphilitic patients that the specific remedies should be given with powerful tonics, and that great care should be bestowed upon the diet.

Disease of the Subcutaneous Mucous Sacs in Children (Albert: quoted from *Journal für Kinderkrankheiten*, 1872, Hefte i.–ii.)—Disease of the subcutaneous mucous sacs is of rare occurrence in children. The author saw two cases in one year, closely resembling each other, both in girls from five to seven years old. Both of the children possessed that peculiar flaccidity in the joint of the ankle which permits abnormal dorsal flexion and pronation, and which may develop into pes valgus.

Although the inner edge of the foot was curved, and the back of it well shaped, yet both children walked with marked tendency to pronation. In each there was a perfect, round, well-distended sac extending from the os naviculare to the inner condyle. The treatment in one case consisted in the application of a plaster-of-Paris bandage, in the position of supination, with a fenestra which permitted the application of topical dressings and pressure. In a few weeks the fluid was absorbed, and a shoe constructed for a case of pes valgus was put on. The same shoe was placed on the other child, but, as it was delicate and scrofulous, the shoe could not be endured, and inflammation of the hygromatous sac set in. Rest in bed, cold applications, and pressure composed the treatment. Suppuration occurred, and an incision was necessary. A flocculent, sero-purulent discharge took place. The case did not show symptoms of rapid improvement.

Subjective Impressions of Color produced by Objective Impressions of Sound (*Wiener Med. Wochenschr.*, 1873, Nos. 1, 2, 3; quoted from *Monatsschr. für Ohrenheilkunde*, March, 1873).—This is an article by J. A. Nussbaumer, which sets forth a peculiarity which he possesses in common with his brother, of perceiving colors subjectively by listening to certain sounds, mostly on the piano. These two gentlemen have been examined by Professor Brühl, of Vienna, who is convinced of the truth of their statements, and, after a careful analysis of the cases, has found that the same sound always produces the same subjective color in the same person, but these colors are not the same in each of the brothers, although the test-sounds are invariable. Thus, the note "small a" on the piano produces in one the subjective impression of dark Prussian blue, in the other dark yellow. There are also colors which are never produced by any sound. Blue and yellow, brown and violet, occur most frequently in one, while blue, yellow, and brown occur most frequently in the other; violet the least frequently.

One of the brothers never perceives red, green, black, nor white, in any musical notes. The author perceived on one occasion green by suddenly hearing a noise from the sharpening of a saw.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 31, 1873.

EDITORIAL.

WHAT HAS BEEN ACCOMPLISHED?

THE annual meeting of the American Medical Association being over, and the report of its proceedings made public, the question may be pertinently asked, What did it accomplish? Our conviction is that upon a comparison of the expenditure and the result, the latter must be admitted to be lamentably small.

We may assume that there was an attendance equivalent to that of four hundred physicians for three days; which would be twelve hundred professional days devoted to the meeting, not counting the time spent by many of the delegates in travelling from their homes to St. Louis and back again. Let us now see whether any object or objects were attained, to the accomplishment of which any one physician would be willing to give up three and one-third years of his time. It seems to us that this is a fair way to put the case.

Of business relating to the affairs of the Association itself, the main item was the establishment of the Judicial Council. That this is a step in advance, will probably be conceded by every one; but we submit that it is but a very short step, since it only provides for the entertainment of ethical and judicial questions, and does not touch the great difficulty, —the non-representative character of the membership of the Association. Of some other matters —the reports of the Committee on Ethics, the report on American medical literature, and that on medical education—we have as yet only meagre accounts, but those contain no salient points offering evidence of interesting material in them.

The Army Medical Corps made an appeal for the memorialization of Congress in their behalf, which seems to have been favorably received, but no action is recorded beyond placing the matter in the hands of a committee.

In regard to the nomenclature of diseases, a subject of great importance to the profession at large, no advance seems to have been made. Much committee-work has been done, and, we believe, done well; but the Association needs to be more "in hand" to make it available by their general action.

One or two propositions were made looking to the establishment of a National Sanitary Bureau; a step which we think in such a country as this would be a great mistake. Far better would it be to leave these matters to the care of the medical men in the various States and regions, to be subjects of study and of competition on the part of those whose interests and opportunities would give them at once the stimulus and the capacity to deal with them.

Assuredly it seems as if this would be but a meagre showing, were it all that one man of average ability could produce in three years of labor. Let us not ignore the social advantage of the friendly meeting of men from different cities and States, or the benefits that individuals may have derived from such contact with their fellows. What we urge, and what we hope to see recognized at some future day, is that the business of the Association must be more positive and practical, more business-like, and transacted by, we repeat, and we may have to repeat many times, a body more truly representing the great mass of active practitioners throughout the United States; not by a mere congress of those whose leisure and inclination happened to make it convenient for them to attend the meeting.

CORRESPONDENCE.

HARVARD UNIVERSITY MEDICAL SCHOOL,
BOSTON, MASSACHUSETTS, May 14, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR:—My attention has been called to an editorial in the *Philadelphia Medical Times* of March 22, 1873, in which the following passages occur:

"The managers of the Medical Department of Harvard University are trying, *we should like to believe with satisfactory prospects*, a system of teaching radically different from that of any other school, at least in this country. . . . And yet there is one most important element,—the financial,—which threatens to fatally affect

the success of the Harvard School." Then Prof. Stillé is quoted as saying, "One institution, to its honor let it be spoken, has re-formed its whole plan of teaching upon the model which reason and experience agree in approving as the best. *Much as I desire in this instance to be a false prophet, I have little fear of meeting with the fate of one, when I declare with unfeigned sorrow my conviction that the Medical Department of Harvard University, which has so heroically undertaken so difficult a task without providing endowments for its professors' chairs, must of necessity fail to secure the success which its liberal policy deserves.*"

Both these writers warmly approve the new system of the Harvard Medical School, and both prophesy while they lament its failure. The last annual report of President Eliot furnished materials for a more hopeful view, which might have mitigated Professor Stillé's sorrow. On referring to Dr. Stillé's published address, a foot-note showed that the report mentioned had been consulted by him, but that the facts therein stated had been overlooked or misinterpreted.

A statement which had proved most encouraging to those immediately concerned had actually been used to strengthen the gloomy foreboding excited by the action of the Harvard Medical School.

We are informed that "Immediately on the adoption of the new system of instruction the number of medical students fell from 301 in 1870–71 to 203 in 1871–2. The Catalogue of the Medical Department from 1872 to 1873 gives the names of 170 students. Under the new system, therefore, the classes have thus far progressively diminished. The receipts have fallen off in the same proportion, and the professors have nearly twice as much work to do, with a remuneration only half as great as they formerly received.

"The result of this arrangement must necessarily be to compel men of real eminence to withdraw from professorships which are so meanly salaried, and to substitute for them young and immature teachers, who will regard their position in the medical college as a passport to reputation and practice, and who are willing to purchase the result by a few years of unrecompensed labor. By this plan the traditions of university education are set at naught, its dignity compromised, and its authority impaired. If any profession requires in its teachers the weight of character which maturity of intellect and ripe experience give, it is certainly the medical; but a plan which virtually excludes such qualifications by refusing to compensate them is too much in opposition to human nature and experience to succeed."

Now, let us look at the facts upon which these statements are based. President Eliot says:

"It having been granted on all hands that these changes were excellent and desirable in themselves, the only ground on which they could be opposed was that they were not feasible, in view of the fact that the entire endowment of the Medical School is only $40,000. The comparison, therefore, of the current receipts and expenses of the years 1870–71 under the old system with those of the year 1871–72 under the new system is of particular interest:

1870–71.

RECEIPTS.

Total receipts from students	$27,717 67
Interest on funds (Hersey, Jackson, Shattuck)	2,779 00
	$30,496 67

PAYMENTS.

For instruction (salaries)	$19,476 82
For janitor and general expenses	10,039 31
	$29,516 13

1871–72.

RECEIPTS.

Total receipts from students	$24,104 59
Interest from funds (Hersey, Jackson, Shattuck)	3,404 62
	$27,509 21

PAYMENTS.

For instruction (salaries)	$20,019 56
For janitor and general expenses	8,877 44
	$28,897 00

The number of students in 1870–71 was 301, while in 1871–72 it was only 203. Yet the receipts from students were only $3600 less in 1871–72 than in 1870–71. Many of the students present in 1871–72 were under the old system, and a considerable portion of these were entitled to gratuitous instruction, under the former rule that students paid nothing for the third year of attendance. The fact is that 150 students present during the year under the new plan would give a considerably larger revenue to the school than 300 did under the old. The corporation *paid rather more* for salaries in 1871–72 than was used for that purpose in 1870–71; but the sum appropriated for salaries was differently distributed. Excluding all items from both sides of the account which were not items of current receipt or expenditure, the deficit for the year 1871–72 was $1387 79.

The corporation had expected a much larger diminution of receipts from students in the first year of the new system, and were more than satisfied with the actual money result.

Let us now compare the deductions of Prof. Stillé with the facts presented in this clear exposition of the condition of the school. The following distinct points are made by the Professor:

1. Under the new system the classes have thus far progressively diminished.

2. The receipts have fallen off in the same proportion.

3. The Professors have nearly twice as much work to do.

4. The remuneration is only one-half as great as that which they formerly received.

5. The necessary withdrawal of these underpaid Professors, and a great variety of consequent evils.

We will now consider these points seriatim.

In regard to the diminution of the number of students, we must admit the fact, but this has been much less than was anticipated. But this diminution has no bearing whatever upon the main question, which is whether the number of students who join the school under the new plan is increasing or diminishing. The following facts show a constant increase. The first

students under the new plan were drawn from the ranks of those who entered under the old. These voluntarily subjected themselves in June, 1871, to the written examinations, as evidence of their appreciation of the change. At the opening of the school in the fall of 1871 a much larger number of new students presented themselves, and in September, 1872, there was still a very marked increase above the number of the preceding year. These statements relate to the first terms of the two years corresponding in time with the old courses of lectures. A still more satisfactory result is seen when we compare the attendance during the second terms, this being the real test of the willingness of students to accept an annual course, which is one of the distinguishing features of this school.

The number of students in the second term of 1872 was ninety-six, of whom twenty-one received gratuitous instruction, in accordance with an old custom to the benefits of which they were entitled. In the second term of 1873 the number rose to one hundred and thirteen, of whom only six were free, and these were sons or assistants of professors. The number not only exceeded that of the corresponding period of the preceding year, but was much larger than that of any class in the summer under the old plan, although then some students joined for a single month, and now all must take the entire term.

The *second* point was that the receipts had fallen off in the same proportion as the students. The latter, according to the figures, had diminished from 301 to 203, or 33 per cent. Mr. Eliot's figures show that the receipts had fallen off 15 per cent. This term *the receipts have exceeded those of the corresponding term of last year.*

The *third* assertion, that the Professors have nearly twice as much work to do, we are glad to say is true in some important departments, to which sufficient time had not been given by the old system. The quantity of teaching has been largely increased; but this increase has been effected mainly by adding to the number of teachers. The Professors whose work has been increased have gladly given the additional time.

The *fourth* statement, that the remuneration was only one-half as great as before, notwithstanding the increase of work, is certainly not derived from the report, as that document states explicitly that *more was paid for salaries than in the previous year.*

Some changes were made in the distribution of this sum, according to the amount of instruction given by the different teachers.

In regard to the *fifth* point, its prophetic character of course makes a final answer impossible at present. It can only be said that up to the present time no Professor has resigned who had not announced his intention to do so before any change was thought of, and every one acquainted with the present composition of the Faculty will admit that it was never stronger than now in professional reputation, and it was never so numerous, so united, or so well satisfied with its work.

The kind of gloomy though pitying prophecy in which Dr. Stillé and the writer in the *Philadelphia Medical Times* indulge is simply one of the natural obstacles which the new system has to overcome. The Harvard Medical School has overcome much more serious obstacles already in contriving and carrying out for two years this great reform in medical education, and has the best prospects of speedy success, in spite of the competition of all the principal schools in the country, which continue to offer medical degrees on the old easier conditions. If five or six of the other leading medical schools in this country would join the Harvard School in making the changes in the system of medical instruction which Dr. Stillé and all other intelligent physicians who honor their profession admit to be desirable, there would be no question in any one's mind about the success of the reform.

Yours truly,

C. Ellis, M.D.,

Dean of the Medical Faculty of Harvard University.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

Semi-Monthly Meeting, May 14, 1873.

Reported by James S. Bailey, M.D.

Dr. Henry March in the chair.

After the reading and approval of the minutes of the last meeting, the Secretary read a letter from the clerk of the Common Council, stating that by resolution of that body the members of this Society were requested to give their opinions in reference to the purity of the waters of the Hudson as a supply for the city of Albany.

By resolution, this subject was ordered for discussion at the next meeting, May 28.

Dr. James S. Bailey stated that one of the members of the Albany County Medical Society, Dr. Peter P. Staats, had completed his fiftieth year in the practice of medicine. He would move, therefore, as customary heretofore, that a committee be appointed to make arrangements for the celebration of Dr. Staats's fiftieth anniversary.

Dr. John M. Bigelow, after seconding the resolution, moved that, as the meeting was not a full one, the resolution be postponed until the next meeting. Carried.

HOSPITAL HYGIENE.

Dr. Isaac De Zouche read a paper on *hospital hygiene.* In the earliest times, before medical colleges had existence, or boards of health had a place among existing institutions, there were, nevertheless, some excellent ideas on the subject of health,—ideas that have not been much improved upon during the last two or three thousand years.

Moses, the lawgiver of the Hebrews, gave very explicit and excellent directions concerning food, cleanliness, and general sanitary regulations, many of which might be followed with advantage even now.

There was something other than mere fanaticism in the Jewish discrimination between clean and unclean beasts, and in their proscription of certain parts of even clean beasts as articles of food. Then their laws in regard to the purifying of parturient women, the cleansing of leprosy, the isolation of all infectious or offensive

cases, the removing of the dead from contact with the living, the frequent ablutions insisted on in all cases, go to prove that Moses was a sanitarian of the most enlightened and practical stamp; a worthy leader of the people in their struggle for a higher life.

The name of the subject, Hygiene, recalls other people than the Jewish. However irrationally the old Greeks and Romans lived, they furnished us with many valuable hints on life, health, and many other subjects.

Their goddess of health, Hygeia, was said to be the daughter of a physician, Æsculapius, who was the son of the god Apollo. To be sure, all this is mythological. The physician does not always spring from deity, nor is his daughter invariably a goddess of health: still, there is enough truth in the myth to warrant its acceptance even now as an article of faith. A subtle meaning underlies the thought that a goddess presides over health: that she sprang from a physician may mean that she was the legitimate offspring of the most advanced expression of sanitary science. But we must leave mythology, however attractive, and come down to facts, however dry. There is, or should be, nothing special in hospital hygiene; for the means by which health may be conserved or promoted should have, and really must have, a universal application.

The hygienic measures essential in a hospital are demanded in every private dwelling, only perhaps there is more urgent need of them in the former, where so many are congregated under one roof and all with health more or less impaired.

The site of a hospital should invariably be in the healthiest part of the city or district, so that in fighting disease the physician should not have native enemies in the camp to contend with. It is of little avail to treat intermittent fevers in a low marshy neighborhood, the home of malaria. "The site of a hospital," wrote the late Edwin M. Stanton, "should be well drained with a subsoil of gravel. The situation should be elevated, as remote as possible from marshes or other sources of malaria, and must have a convenient supply of pure water."

In an elevated situation we have the requisite condition for good natural drainage; but even then we must have the subsoil of gravel, for if it be of clay there is sure to be an injurious amount of moisture, and this subsoil moisture plays no mean part in the inception and continuance of many infectious and epidemic diseases. The high situation and natural drainage insisted on are not intended to supersede artificial drainage, but rather to divide or supplement the work of keeping the site as free from dampness as possible. Hammond urges strongly the necessity of examining into "the character of the soil and subsoil, for if the site be chosen regardless of these points, disease, either fevers, bowel-affections, rheumatism, or catarrh, will inevitably be produced."

Besides the natural drainage which is the result of an elevated situation, we have as a second important result a much freer circulation of air than is possible on a low level; and this is almost as important as the drainage. Stagnant air is as much to be feared as stagnant water.

The drains leading from the building should be so planned that their course towards the main sewer shall be as direct as possible, without unnecessary angles or tortuosities.

In their construction it would be well to remember that *stagnation* is *death*. There should always be provision for a stream of water passing through, to carry the sewage with it and prevent any accumulation of organic refuse. There should be at the same time good drain-ventilation,—the ventiduct leading to the top of the building,—that the noxious sewer-gases may not invade the house, bringing typhoid and other diseases in their train.

The best plans for hospital buildings, according to the best-informed authorities, embrace what is known as the pavilion system; that is, separate buildings, or wards totally separated from each other, merely accessible by a common corridor.

The space between any two wards should be sufficient to preclude the possibility of the spread of contagious diseases or matter through the open windows. With this form and arrangement of a hospital we secure two very important points,—a free circulation of air, and unobstructed light.

It would be all the better if these separate buildings were only one story high; but space is usually too valuable in situations suitable for a hospital to permit of so great a sanitary luxury.

When there are two or three stories, the separation of each from all the others should be as complete as possible. There should not be any openings directly from the lower wards into the upper.

The stairways should be so placed that the foul air from below cannot ascend through them to mingle with the air of the upper wards. The true principle of ventilation is to provide for all impure air being carried away out of the building from each floor.

When the windows of the lower wards are open, I would recommend that over each there should be a projecting canopy, arranged in such a way as to lead the impure air from the ward as far out from the face of the building as possible, so that no portion of it shall enter the open windows of the upper wards.

The floors should be far more solid and air-tight than contractors usually make them, and between the rafters there should be a packing sufficient to bar the passage of air from below, and at the same time to deaden the sounds of feet and other noises above.

In an address to the Southampton Medical Society, Langstaff lays much stress on the importance of having a great number of small separate rooms, instead of the few large ones which we constantly find in large hospitals; but, as we cannot hope to see any great change in the construction of existing institutions of the kind, he proposes to make the best of what we have. He, as well as other physicians whom he mentions, has found that the floors and walls of a hospital after continued use absorb matter which leads to the outbreak and spread of diseases, and that it is needful to apply to them a new absorbent material and one that can readily be cleansed. Recognizing the great value of lime as a purifier, he nevertheless believes that whitewashed walls very soon absorb the poison from the sick-bed, and require to be frequently removed.

The best method, he believes, of rendering hospital walls and ceilings non-absorbent, is to paint them on a smooth surface with several coats of paint, and finally varnish them.

The floors might be made non-absorbent by painting them with hard paraffine previously melted in an iron vessel, and ironed in with a box-iron heated from the interior with charcoal.

Under no circumstances should there be paper on the walls of a hospital ward or carpet on the floor, as they absorb and retain for an indefinite period the poisonous germs that arise from disease, and thus render the room unsafe for future occupants. Neither should patients, nurses, or house physicians wear woollen articles of clothing, as they tenaciously hold the "hospital smell," which is always at least suggestive of contagion.

In ordinary dwellings, where the inmates are as a rule healthy, the usual means of ventilation by windows and doors answer the purpose very well; but in a hospital, where medical and surgical diseases prevail, and

the air becomes laden with the foul exhalations from every variety of decaying tissue, it is of the utmost importance to take advantage of every means by which pure air may enter and the impure escape most effectively.

Now, pure air, as a rule, enters a living-room at the lowest openings, whilst the air which has become vitiated by having passed through the lungs, or contaminated by contact with the exhalations from the surface of the diseased body, ascends to the top of the room, and will escape more or less completely by the highest openings. I qualify the statement, believing it will not wholly escape unless the highest openings are at the highest point in the room, on a level with the ceiling. The lower openings should be at or near the level of the floor.

The exhaled air is largely composed of carbonic acid gas, which, at the same temperature as the pure air, is much heavier than it, volume for volume.

When first exhaled, being expanded by heat, its specific gravity is less, and it ascends, to escape measurably by such openings as there may be; but if proper provisions have not been made above for its departure at this time, it quickly condenses and sinks to the lower part of the room, where it is destined to struggle with the pure air, provided there are inlets.

Now, if there are openings at the level of the floor on all four sides of the room, there will be better opportunity for the accumulation of this poisonous gas, which would escape on the side of the room which sailors call "leeward," impelled by the pure air entering at "windward." The upper openings in the room should be somewhat larger than the lower, for obvious reasons; and I think it important that they should be at the level of the ceiling. When this is neglected, there will always be a reserve of deleterious gases found hovering about the angles, and tainting the whole upper stratum of air in the room, to the great detriment of the patients, to whom the oxygen of the pure air is even more essential than calomel or quinine.

Water-closets should invariably be placed at the boundary walls, each with a window admitting an abundance of sunlight and giving the opportunity for the ingress of pure and the egress of noxious air, and all this besides the ventilation proper to the soil-pipe. Water-closets should never be constructed in dark corners in the centre of a building; for, however thorough the system of ventilation may be, there will always be at least a strong suspicion of impurity in the air,—a suspicion that will hardly bear the test of chemical analysis.

A bath-room on each floor, to which patients should be introduced on admission, and obliged to use at least twice a week during their stay in the hospital, will prove a valuable auxiliary in the sanitary work. With good drainage, a constant supply of pure air, and a persistent regard for personal cleanliness, the doctor's work would be simplified and the proportion of good recoveries be greatly increased.

The regulation of the temperature is a matter of very great importance, and, I may add, of great difficulty too, with such heating-apparatus as we find generally in use. So long as the air we breathe is kept below 65° Fahrenheit, it acts as a stimulant to the lungs, which accordingly work with more vigor to keep up the heat of the body in the natural way. Combustion goes on more or less perfectly, and the effete products of decay are rapidly expelled from the system. But when we permit the temperature of the living-room to reach 70° or upwards, nature recognizes the wrong and protests against it. The lungs, to be sure, do not cease to act, but they seem to lose time and work more languidly; the combustion of effete material going on so slowly, much of it lingers in the system to poison the blood and deaden the fire of life.

The effect of continuous high temperature, especially when artificial, on even healthy people, is a relaxation of muscular fibre, superinducing a listlessness almost amounting to paralysis of the will.

Special care should be taken to classify patients according to their diseases and the measure of their sickness. Cases of erysipelas, hospital gangrene, some fevers, and contagious diseases, which may have found their way into the hospital or become developed there, should be isolated in the upper story of the hospital, when it consists of more than one story.

During the prevalence of erysipelas, hospital gangrene, syphilis, etc., sponges should never be used; tow or rags, which should be burned after once using, might be substituted with advantage in dressing wounds and ulcers.

In regard to the size of hospitals, there is a growing belief that the larger they are the worse it is for the patient. Amputations become more dangerous and fatal in proportion as the hospitals in which they are performed increase in size. By separation and isolation the patients recover with more certainty. The safety is in segregation, the danger in aggregation. In the Edinburgh *Monthly Journal of Medical Science* for November, 1848, Sir James Y. Simpson wrote on this subject an article in which will be found the following: "Perhaps one of the most weighty and momentous questions to which the physician, the surgeon, and the accoucheur can direct his attention is the proper reconstruction and arrangement of our hospitals. The vast importance of the subject depends upon this point, that it involves the study and rectification of influences that set utterly at defiance all the proudest advances of practical medicine."

Sir James speaks of the signal and striking progress made by surgeons during the last fifty or one hundred years, in various ways, and yet, notwithstanding all that, the proportion of fatal results of operations has been steadily increasing. "Amputation, for instance, as an operation, has, like many other operations, been mightily improved in the modes of its performance, in the modes of arresting attendant hemorrhage, in the modes of dressing the stump, etc.; but still in these hospitals [the infirmaries of Edinburgh and Glasgow] the mortality from limb-amputations has, since the last century, become increased instead of diminished. The increase is traceable, I believe, chiefly or entirely to our system of huge colossal hospital edifices, and to the hygienic evils which the system has hitherto so much involved.

"I have often stated and thought that if our present medical, surgical, and obstetrical hospitals were changed, from being crowded places with a layer of sick on each flat, into villages or cottages with one or at most two patients in each room, a great saving of human life would be effected."

To substantiate what he says, Sir James gives facts and figures which throw much light on the subject. The following are suggestive tables showing the proportionate mortality of limb-amputations in Great Britain as regulated by the size of the hospital and the degree of aggregation or isolation in which the patients are placed:

1. In hospitals containing 300 to 600 beds, 1 in 2½ die.
2. In hospitals containing 100 to 300 beds, 1 in 4 die.
3. In hospitals containing 25 to 100 beds, 1 in 5½ die.
4. In cottage hospitals containing under 25 beds, 1 in 7 die.
5. In isolated rooms in country places, 1 in 9 die.

These few figures teach a lesson of vast importance in relation to hospital hygiene; and they seem to discourse so plainly as to require no comments.

In studying the sickness and death-rates of communities and all the conditions under which we get the

statistics relating to them, we furnish ourselves with the weapons necessary to fight and conquer a thousand ills that decimate the population of our cities.

The proportion is large of those who die from preventable causes, to some of which I have referred in this paper.

This subject is well worthy of our consideration as physicians; and this fact has induced me to address you in regard to it.

RHEUMATIC PERITONITIS.

Dr. JOHN M. BIGELOW said that rheumatic peritonitis is regarded by some as a hypothetical disorder, by others as extremely rare.

Niemeyer remarks, "Peritonitis very rarely occurs in persons previously healthy, and its occurrence in them is due to catching cold or to some unknown atmospheric influence. It is then called rheumatic peritonitis."

Rokitansky asserts that "spontaneous or rheumatic peritonitis exists," and attributes it "to the metastasis of anomalous exanthematous processes or of rheumatic poison which tends to exudation;" but he fails to inform us of the nature of the morbid material or of its method of generation.

Flint observes "that exposure to cold may originate peritonitis," and, excepting by reference, says nothing of the probable origin of peritonitis as due to poison in the blood.

Habershon, from an analysis of five hundred cases of peritonitis, explicitly asserts that "peritonitis is never idiopathic in its origin, but when not traumatic or due to perforation of the viscera it is dependent on either an extension of diseases from adjoining viscera or on certain blood-changes, such as occur in albuminuria, pyæmia, rheumatism, etc."

Todd also indirectly affirms this conclusion by stating that "the poison of rheumatism is akin to that of pyæmia as the originator of peritonitis." Tanner strengthens these statements by ascribing as a cause of peritonitis "the contamination of the blood by morbid poison." Rheumatism is now regarded as the product of a morbid intrinsic alteration of the blood, by which lactic acid, a morbid poison, is produced: hence Tanner may by implication support Habershon's statements.

We also assert that previous attacks of rheumatism in early life from six to ten years of age furnish a predisposing cause to the subsequent peritonitis of youth or of adult life. This may afford an explanation of the origin of an attack of peritonitis otherwise inexplicable.

Again, we sometimes, though very seldom, meet with a family among whose members the slightest cold or digestive derangement provokes pains in the joints and muscles, and a general pyrexia. In a few days these symptoms disappear suddenly, and, coincident with their cessation, tympanitis, abdominal pain, troublesome diarrhœa, "colicky" pains, and a severe illness of several days' duration, set in. Sometimes, though very rarely, sudden death occurs. In these last cases there would seem to be a hereditary predisposition to rheumatic fever, and to the election of the peritoneum as the especial object of the baneful attack. When we recollect that after the puerperal state sometimes symptoms of ordinary rheumatic fevers are manifested, such as the profuse sweat, the swollen joint, the intense fever, the lithic-acid urine,—in fine, a state called by some French writers "puerperal acute rheumatism," due to some inflammation of the uterine veins which infects the blood and begets articular, peritoneal, and other inflammations,—when we recall such instances of the action of morbid material in the blood, why should it be deemed incredible that in the course of an attack of rheumatic fever a "morbid poison" due to some vital hæmatic change induced by disease may be born in the blood, and finally select the peritoneum, a serous membrane, as its particular prey?

The rheumatic poison does frequently attack the heart, the pericardium, the pleura, serous membranes, the meninges of the brain: why, then, can it not invade the peritoneum, a serous membrane, and even more likely to recover when attacked?

ANATOMICAL CHARACTERISTICS.

We have only seen the autopsy of one case of so-called rheumatic peritonitis. The lesions were those of diffusive peritonitis. The exudations were, however, serofibrinous, and abundant lymph was plentifully present, and formed a thin coating over the hollow viscera and other parietal portions of the peritoneum. The peritoneal sac contained a fluid turbid with lymph. More or less abundant small abscesses were also scattered throughout the intestines, and were found to contain a sero-purulent fluid of a greenish cast. Cleared of exudation, the peritoneum was brittle, softened, and in spots deeply injected.

The adhesions between the intestines and other viscera were slight and easily separated, and very extensive, compassing the whole peritoneal cavity.

The urine was rather scanty, of a deep saffron color, specific gravity 1029, and exhibited traces of the urates, and was also slightly albuminous. Excepting a slight effusion in the chest, there was no evidence of any previous disease of the pleura or lungs.

CLINICAL HISTORY.

Rheumatic peritonitis is of a gradual development. A chilly feeling prolonged and general, or a severe chill, with subsequent pains in the joints or neck, a sense of general soreness, "a pounded feeling," admonishes the subject that some sickness threatens. There is slight fever, exacerbating towards evening; a dark puffy appearance under the eyes also is apparent. This condition may last for two or three days, when there will be noticed a tendency to an intermittent colicky diarrhœa, flatulence, depression of spirits; furred tongue, which in the morning may be rather dry and glossy, but towards evening becomes slightly moist, pallid, and flabby around the edges; anorexia; the chin at times becomes slightly rosy, the mouth pallid, the sleep restless; the subject complains of "a bad cold which has settled over the whole system," and of a pain in the abdomen, for which pressure, cathartics, or other remedies fail to bring relief.

The temperature at this time ranges from 102¾° Fahr. evening to 101¼° Fahr. morning; the pulse from 100 to 130 per minute.

A slightly heavy feeling in the top and back of the head is complained of; great prostration, disproportionate to the severity of the symptoms present, is noticeable.

Or, again, the sufferer will be laboring under a rather mild attack of acute articular rheumatism; or, thirdly, rheumatic fever in its most painful form may plainly exhibit itself. In all these cases the unusual prostration above mentioned enforces early attention.

This attack of apparently rheumatic fever in its mild or more aggravated form fails to yield to the usual measures, when suddenly the articular pains cease; a sense of general chilliness is now complained of, and abdominal pain and tenderness are markedly present; in a short time symptoms of diffusive peritoneal inflammation clearly show themselves. The change of the attack is abrupt; the peritoneal disease is quickly declared, and is in most cases supplemental to the sudden disappearance of general physical disturbance.

Continued pain is a very prominent symptom; it is generally diffusive; very rarely it is wanting; occasionally it is paroxysmal; coughing, sneezing, and deep

inspirations aggravate the pain; the respirations are consequently shortened in length and increased in frequency.

Pressure and sudden change of position likewise produce severe distress. The knees and thighs are generally fixed; though sometimes the dorsal or lateral decubitus is tolerated and affords great relief.

Tympanitis is always present to a considerable extent; constipation, due to paralysis of the muscular coat of the bowels by collateral œdema, is the rule; diarrhœa is a not unfrequent exception; vomiting seldom occurs. The pulse is frequent and small,—120 to 135 per minute; the temperature fluctuates between 101½° Fahr. to 103° Fahr. or even to 106° Fahr. The mind is generally quite clear; muscular rigidity is frequently present. As the abdomen becomes distended with flatus, the intestines, now literally blown up with gas, press up against the diaphragm, causing compression of the lower lobes of the lungs, excessive hyperæmia of the uncompressed portion, and dyspnœa. This disturbance of the pulmonic circulation may extend to the venous system and impart to the patient a cyanotic hue.

"The anxiety of the patient is painful," and the alternate appeals for relief and utter despair reflect his intense bodily suffering and mental anxiety. At last the mind becomes cloudy, the sufferer grows apathetic and delirious,—sometimes comatose; the pulse becomes smaller and more frequent; the body is covered with a cold sweat; asthenia supervenes, and the patient succumbs to the malady.

Should the subject linger for some time, the tympanitis decreases, but never wholly disappears; the fever exacerbates, consumes the strength and every tissue; the skin becomes dry and scaly, the muscles flabby and relaxed, the limbs swollen and œdematous, and death occurs in the third or sixth week by asthenia.

Convalescence, if established, is tardy and lingering; it is attended by more or less colicky pains, abdominal tenderness, and asthenia. Three or four months may elapse before natural vigor and strength begin to return.

Most of those attacked with peritonitis die of the disease, "not because this affection is particularly ill borne by the organism," says Niemeyer, "but because it depends on the severe blood disease;" and he further observes, "We frequently see the rheumatic peritonitis which occurs in otherwise healthy persons terminate in cure, providing the exciting causes be removed soon enough."

Flint states that in uncomplicated cases the prospect of recovery is good under judicious and early treatment. This peritonitis may destroy life in twenty-four hours or in fourteen days. The average duration, when convalescence or tardy development of the disorder does not take place, is five or six days.

The significant symptoms of rheumatic peritonitis are the sudden cessation of general articular pain and rheumatic symptoms, and the almost concurrent pain, tenderness, and tympanitis in the abdomen; besides these symptoms, undue prostration and laborious dyspnœa indicate great danger. The mode of death is by asthenia. As Flint observes, "a progressive increase of the frequency and feebleness of the pulse, progressively increasing prostration, coldness of the hands and feet, hiccough, etc.," presage an unfavorable advance in the disease.

When these symptoms improve, and the tympanitis and muscular rigidity diminish, we may entertain hopes of recovery, or, at least, of delay of the more imminent symptoms of death.

DIAGNOSIS.

Peritonitis is readily diagnosed from all other diseases after its development, as the tenderness on pressure, tympanitis, "colicky pain," and "belly-ache," at once distinguish it from all other disorders. Rheumatic colic, lumbo-abdominal neuralgia, hysteria, mesenteric neuralgia, hyperæsthesia of the skin of the abdomen, may each simulate peritonitis; but a careful study and analysis of the symptoms, and the amenableness to treatment of the above disorders, and the stubbornness with which peritoneal difficulty yields to remedies, as well as the element of time, will generally afford an easy discriminative diagnosis.

TREATMENT.

The treatment of rheumatic peritonitis consists mainly in rest, opium, and permanganate of potassa, with a liberal use of nourishing beef-broths, milk, and alcoholic stimulants. When there has been time to prescribe for the rheumatic disorder prior to the peritoneal invasion, permanganate of potassa in $\frac{1}{12}$ grain doses should be given every hour; the bowels should be opened by an enema, and opium given freely, so as to relieve pain, subdue inflammation, and secure rest. Gelseminum also has been recommended, and, by some, is said to be successful when given in the form of the fluid extract in three-minim doses every hour. Quinine also may be employed with a view to its tonic effects. Externally, leeches, rubefacients, turpentine, also spongio-piline and hot-water applications, are well spoken of by authors. Besides these, Niemeyer says "that cold compresses to the abdomen exert a most beneficial effect;" and he agrees fully with those who consider the application of leeches to the abdomen, the use of cold compresses, and the internal administration of opium as the most effective treatment.

Flint and Professor A. Clark each assert that our main reliance in treatment is opium, given fully and freely.

Cathartics, mercury, and blisters are alike condemned by most clinical observers and successful practitioners; although there are those who affirm that epispastics do frequently afford relief, and that mercury does arrest or check the inflammation.

When an early dyspnœa and cyanosis admonish us of the imminence of fatal symptoms, venesection as a temporary expedient may, as Niemeyer observes, be resorted to; for we know of no other remedies to fulfil this urgent indication.

To relieve vomiting, ice is best administered; to check the diarrhœa, opium is to be preferred to all other astringents: as the flux is due to œdema of the intestinal mucous membrane, opium is as beneficial as astringents. When convalescence is established, cod-liver oil and quinine should be liberally prescribed. If the exudation be great, iodide of potassium and acetate of potassa in small doses should, if borne, be ordered in connection with the various preparations of calisaya bark. Above all, fresh air, judicious exercise in the open air, nutritious diet, and quietude of body and mind, should be strictly enjoined.

Cathartics should be given with great caution, and not for at least six weeks after recovery; enemata are to be preferred.

The tendency to frequent relapses should always be borne in mind, and fatigue, exposure to cold, and inattention to diet strictly forbidden.

We shall now narrate the history of a few cases illustrative of this subject.

M. B., æt. 18, by occupation a shop-girl, was attacked by acute articular rheumatism on February 12, 1873, and presented all the symptoms of this disorder for two successive weeks, when on the morning of the 26th of February the articular pains suddenly subsided, and abdominal tenderness, tympanitis, and the symptoms of rheumatic peritonitis developed themselves in the sequence mentioned in this paper. The undue prostra-

tion was early manifested, the fluctuating temperature from 101° to 105° Fahr. plainly present. The permanganate of potassa in $\frac{1}{16}$ gr. doses, opium freely and pro rata to the disease, nourishing broths, and turpentine stupes, constituted the treatment. After an illness of seven weeks she recovered, but at the present time she has not by any means regained her wonted vigor or strength.

J. H., male, æt. 21, carpenter, was attacked, December 23, 1872, with slight symptoms of rheumatic fever; complained of a "pounded feeling" over the whole body, and of general soreness; had no articular pain excepting in the wrist. About one week afterwards he was attacked with peritonitis.

Under the treatment previously spoken of, recovery took place, so that he resumed his occupation March 18, 1873.

In addition to these, we have the notes of two other cases which have recovered under appropriate treatment, as well as the record of two cases which died, one in four days, the other in two weeks after the first symptoms of general peritoneal rheumatic disorder developed themselves.

Were it not for the full description of this malady—rheumatic peritonitis—in our preceding remarks, we should give in ample detail the clinical notes of the above cases.

(To be continued.)

REVIEWS AND BOOK NOTICES.

A Hand-book of Medical Electricity. By Herbert Tibbits, M.D., L.R.C.P. Lond., etc. 8vo, pp. 164. Philadelphia, Lindsay & Blakiston, 1873.

Dr. Tibbits is already favorably known as the translator and editor of Duchenne's "Localized Electrization," and the work he now offers to the profession will, we have no doubt, be well received. As he has large experience, both in hospital and in private practice, he is well fitted for the task he has undertaken.

The object of this book is to give to physicians in general a practical and concise treatise on the employment of electricity as a therapeutic agent, and, avoiding all mooted questions, to collect from the best authorities whatever is important on the subject. The author expresses a desire to place the matter before his readers in such a way as to make them "as much at home with their electrical as with their other instruments." This ought to be the case. Electricity is becoming every day better known as a means of great value in the treatment of certain forms of disease; and, as batteries are now being extensively made, and at a much lower price than formerly, every physician should have this form of treatment at his disposal.

The instruments described in the first part of the book are only those which Dr. Tibbits, from personal experience, believes to be the best. With the exception of Stöhrer's apparatus, they are not much known in this country, and, judging merely from the description given here, they are not superior to our own batteries. Foveaux's portable battery for the constant current, which is recommended, besides being open to several objections, is by no means reasonable as to its cost. The price is £15 15*s.*, or about $88 currency, for a sixty-cell apparatus.

The manner of applying electricity is very clearly and admirably explained, and minute directions are given for the indirect method of electrization. This latter subject would, we think, be made more valuable by the introduction of Ziemssen's diagrams, which show the points of entrance of the motor nerves into the muscles.

In some instances the directions for electrizing the various organs are not so explicit as they should be. For instance, to galvanize the bladder we are simply told to introduce one electrode into this organ and another into the rectum; but we are not told how long the current should be allowed to pass, nor how strong it can be borne. In some cases the voltaic current causes considerable urethral irritation. In regard to electrization of the uterus, the only directions given are to apply the plates of a uterine electrode so that one will be on each side of the cervix. Nothing is said of intra-uterine electrization.

The author speaks in high terms of Dr. Radcliffe's method of applying electricity. This consists in charging the patient with the positive current. The plan is said to have been successful in some instances where other means have failed.

Franklinism, which has fallen greatly into disuse, is discussed at some length. In the hands of Dr. Tibbits it has proved of value, and it is recommended to be tried where faradism has failed. It is most useful in hysterical aphonia and in the various forms of tremor.

The chapter on electro-therapeutics gives several illustrative cases, which show strikingly the benefits to be derived from this form of treatment.

Although as a whole the work is very valuable and we strongly recommend it to all who propose to use electricity, it would have been better had it gone somewhat into the elementary science of the matter. There is no description of the modus operandi of batteries; and unless a physician is acquainted with this part of the subject, he is not fully competent to make use of electricity.

The book is a reprint from the English edition, and is well gotten up. The printing, paper, and binding are as good as possible. The less said about the illustrations the better; but they are no worse than in the original copy.

Notwithstanding the apparent good size of the volume, the print is so large and the margins are so wide that there is comparatively little reading-matter. The whole book can be read through in an evening.

Had some of the larger woodcuts, which are of no use to any one, been omitted, the volume could have been made much smaller, and the price reduced one-half.

The Mechanism of the Ossicles of the Ear and Membrana Tympani. By H. Helmholtz, Professor of Physiology in the University of Berlin, Prussia. Translated from the German, with the Author's permission, by Albert H. Buck and Normand Smith, of New York. With twelve Illustrations. New York, William Wood & Co., 1873.

We hail with pride the appearance of an English rendering of this invaluable work of the great physiologist; for, as the translators say in their prefatory notice, this treatise, which first appeared in *Pflüger's Archiv für Physiologie*, Bonn, 1869, "is the only treatise in any language which enters fully into the anatomical, physiological, and mathematical aspects of the question, and will undoubtedly remain, for many years to come, the authoritative treatise on the subject."

The book contains sixty-three octavo pages, divided into eight chapters; the first four having been translated by Dr. A. H. Buck, and the remaining four by Dr. Normand Smith.

The subjects treated of under these eight heads are as follows:

1. Results due to the small dimensions of the auditory apparatus.
2. Anatomy of the membrana tympani.
3. Attachments of the malleus.
4. Attachments of the incus.

5. Movements of the stapes.
6. Concerted action of the bones of the ear.
7. Mechanism of the membrana tympani.
8. Mathematical appendix: having particular reference to the mechanism of curved membranes.

"The membrana tympani is not to be considered as an elastic, yielding membrane, but as an almost inextensible one. This peculiarity of construction of the membrana tympani is a very important element in the mechanical working of this membrane." This is the substance of the second chapter.

In the third chapter the important "axis-band" of the malleus is explained, besides the other complicated ligaments which hold this bone in its proper place.

In the fourth chapter the author describes the true nature of the malleo-incudal joint, as discovered by him.

"The shape of the last-named articular surface is usually described as resembling a saddle." The author, however, rejects this description, and says, "In order to gain a clear idea of the mechanism of this joint, it is better to make use of a different comparison than that of the surface of a saddle. It is, in fact, like the joint used in certain watch-keys, where the handle cannot be turned in one direction without carrying the steel shell with it, while in the opposite direction it meets with only slight resistance." As in the watch-key, so here the joint between the hammer and the anvil admits of a slight rotation about an axis drawn transversely through the head of the hammer towards the end of the short process of the anvil; a pair of cogs oppose the rotation of the manubrium inward, but it can be driven outward without carrying the anvil with it. This is perhaps the most important fact stated in the work.

The mathematical appendix, besides possessing its native difficulties, is vague in some parts of its translation, and on page 67 the word "*restore*" should be changed for the word *reduce*.

In the formulæ which follow, the radical sign should not be extended over *cos* ω in the equation of *r*, nor over *sin* ω *d*ω in the equation of *dv*. This inaccuracy does not occur in the original.

The translators have, as we think, judiciously, used Saxon words in the translation of the kindred German words. Thus, "*Nabel*" is translated *navel*, "*Hammer*" *hammer*, and not "*malleus*," "*Amboss*" *anvil*, not "*incus*," "*Steigbügel*" *stirrup*, not "*stapes*;" it is hardly, therefore, fair to translate the good old word *Gehörgänge* by the spurious Latin plural *meati*. We may perhaps be excused for lamenting the use of this unknown case of the word *meatus*, which, as we all know, is a regular noun of the fourth declension. Its plural, therefore, should be *meatus*, and not *meati*, as it stands in two places in the foot-note on page 41.

We may add, however, that these are but slight defects, in comparison to the real worth of the book, and we congratulate the readers of otological literature upon the reception of this, perhaps its richest gem.

C. H. B.

FAMILY THERMOMETRY: a Manual of Thermometry for Mothers, Nurses, Hospitalers, etc., and all who have Charge of the Sick and of the Young. By EDWARD SEGUIN, M.D. Crown 8vo, pp. 72. New York, G. P. Putnam & Sons, 1873.

This is rather a quaintly written work, the general scope of which is sufficiently indicated by its title. There is much in it which is true and good, although we cannot reckon among all the mothers of our acquaintance a single one who would be likely to accept and follow it as a guide.

Dr. Seguin would have every mother furnished with two thermometers; one like the ordinary instrument for medical use, the other with its bulb flattened down for application to surfaces. In each, the zero is to be the normal temperature of the body, or 98.6° Fahrenheit, and the plan is thus shown (page 13):

"PLAN OF THE MOTHER'S THERMOMETER.

Degrees above o	7	No well-authenticated recovery.
(thus written):	6	Generally death.
	5	Often fatal.
	4	High fever.
	3	Considerable fever.
	2.5	Moderate fever.
	1.5	Slight fever.
	o	Standard of health, NORMÆ.
Degrees below o	.5	Sub-normal.
(thus written):	1	Depression.
	2	Collapse.
	3 to 4	Algid collapse.
	4 to 5	No known recovery, except in cholera."

A chart for recording the temperatures, pulse, and respiration, for the period of a week, is given at page 15.

Our author goes into this whole matter (and many others) with much Gallicism and expansion, and often in a style far above the comprehension of mothers of ordinary calibre of mind. We can scarcely think his labors will have a very wide influence, although we concede the soundness of his views and the justness of his teaching.

THE PASSIONS IN THEIR RELATIONS TO HEALTH AND DISEASE. Translated from the French of Dr. X. BOURGEOIS, by HOWARD F. DAMON, A.M., M.D. Small 8vo, pp. 201. Boston, James Campbell, 1873.

A book more suggestive of evil has seldom been submitted to us for review. We do not think there was any occasion for the writing of it for French readers, or for the translating of it for the American market. It is much to be regretted that Dr. Damon has given the sanction of his name to such a work.

GLEANINGS FROM OUR EXCHANGES.

SUDDEN DEATH FROM THE LODGMENT OF FOOD IN THE BRONCHIAL TUBES.—By Dr. Féréol (*Le Mouvement Médical*, April 26, 1873).—Dr. Parrot pointed out, five years ago, a cause of sudden death in young infants, which has not since, in France at least, attracted the attention of physicians. An infant, after being nursed, is put to bed in perfect health; on the following day it is found to be dead, or else it awakens in the night, and is taken with vomiting and dyspnœa, by which it is quickly carried off. At the autopsy, the bronchial tubes are found to be filled with coagulated milk, and the neighboring pulmonary tissue is found to be softened and to exhale an odor of butter.

Dr. Parrot has lately reported to the Biological Society (see *Le Mouvement Médical*, No. 13, p. 163) another case similar to the one reported by him in 1868.

Dr. Féréol states that he had under observation in 1869, in the Hospital for Incurables, a patient whose case, notwithstanding the difference in the age, nature of the food, etc., bore a strong resemblance to the cases reported by Dr. Parrot. The history of the case is as follows:

Antoine L. was admitted, when a young man, into the Hospital for Incurables. He is now 55 years of age; his intelligence has always been of an extremely low

degree; his appetite is extraordinarily voracious, and the patients and attendants of the hospital often amuse themselves by giving him portions of their food or wine. The unfortunate man often suffers from dreadful attacks of indigestion, brought on by his insatiable gluttony. Sweats occur during these attacks; but the patient always recovers promptly, after vomiting and by rest in bed.

On the 8th of September, 1869, however, an attack of more than usual severity made him so ill that he had to be admitted into the infirmary. The attack was one of apoplectiform indigestion, which came on after the patient had gorged himself with wine and food of various kinds. His face was cyanosed, the extremities were relaxed, the breath had a distinctly alcoholic odor, and the patient was absolutely insensible to everything employed to arouse him. An emetic failed to have any effect, and dry and wet cups and sinapisms made no impression. The patient died at four o'clock in the morning, without ever having become conscious. At the autopsy the stomach was found to be considerably dilated and to be filled with a pulpy matter of a blackish color and having a sour and somewhat alcoholic odor. Pieces of undigested cabbage and fruit were also found, and the quantity of undigested matter in the stomach amounted, without exaggeration, to about three litres. The mucous membrane of the stomach was thin, soft, of a dark violet hue, and injected in an arborescent manner.

Masses of partially digested cabbage and lentils were found in the ileum and in the large intestine, as far down as the rectum. The right lung was perfectly healthy; half of the lower lobe of the left lung was hepatized, and presented the characteristic granulations of the second stage of pneumonia; the hepatized tissue was dense, and, when placed in water, quickly sank to the bottom. On opening the left bronchus and its ramifications, the mucous membrane was found to be of a violet-red hue, contrasting strongly with the normal color of the membrane as seen in the right bronchus. Further dissection of the bronchial tubes on the left side revealed a grayish material and fragments of foreign bodies, which at first sight were recognized as pieces of cabbage. Microscopical examination dispelled all doubt as to the vegetable nature of these fragments. The heart was healthy; in the aorta there were a few atheromatous patches, and a few of the same were found in the cerebral arteries. The brain weighed 1300 grammes, and did not present any marked lesion to the naked eye; there was a slight serous effusion in the meshes of the pia mater, and the meninges were slightly injected.

Without doubt acute alcoholism may have taken a certain part in the production of symptoms so rapidly fatal, but it is no less certain that the pneumonia, which itself advanced so rapidly, had for its special cause the passage of food into the bronchial tubes. It is probable in this case that, during the efforts at vomiting, regurgitation into the larynx occurred.

The analogy that exists between this case and those reported by Dr. Parrot is evident, and helps to strengthen the observations of our colleague.

Case of Resuscitation of a New-Born Infant after nearly Four Hours' Artificial Respiration (*Medical Press and Circular*, March 26, 1873).—Dr. J. Marshall, of Limerick, gives the details of an interesting case which demonstrates the value of artificial respiration even in cases that appear to be nearly hopeless. Dr. Marshall was sent for to attend a woman in her third pregnancy. She had been "attended" up to the time of her admission into hospital by an ignorant midwife. On examination he found the right arm and funis (pulsating) in the vagina, and, having returned the funis, he "turned" and delivered the patient of an apparently lifeless male child, so much so indeed that the funis was divided, without ligature, to see if any blood would escape from the child, the placenta having been born with the head. Not a drop of red blood issued from the cord, and the child never cried; while slapping, cold-water sprinkling, and brandy application failed to elicit the welcome symptom of life. However, when placed on a table and in the light, the pulsations of the heart were faintly visible; so artificial respiration was at once resorted to,—the first method tried being that of having one to breathe into the infant's lungs, and another to expel the air from the same. The infant, having been laid on its back and rolled in a warm blanket, was so placed that the head extended over the edge of the table, and was allowed to droop a little to prevent the air passing into the stomach. The child's face was next covered with a towel, and, the little nostrils having been compressed by the left thumb and forefinger of the operator (his right supporting the head), air was regularly but forcibly breathed into the lungs, and again expelled from them by an assistant's pressing alternately with his two palms on the infant's chest; brandy being vigorously rubbed into the chest by an attendant. The treatment, *after an hour's* steady prosecution, and the heart's action scarcely detectable, was rewarded with one voluntary inspiration, but had to be immediately renewed after the gasp, which showed no signs of recurrence without the artificial respiration. Another single gasp occurred in half an hour, but the inflation, etc., had to be kept up, as the breathing-apparatus had no strength whatever. Seeing the heart beating even so weakly, the attendants could not, nor were willing, to abandon the little struggler, and each took his turn at the "breathing;" the child got a couple of hot baths. Sylvester's and Marshall Hall's treatment were both tried, till, from a combination of all these remedies, the infant was breathing regularly at the rate of fifteen per minute, after *being inflated for nearly four hours*, Dr. Marshall not leaving till five o'clock, about half an hour before which time the first drop of blood from the funis tinged the water of the hot bath, in which the child was kept during its convalescence. Out of all the methods of resuscitation employed in this case, the breathing-in and expulsion of warm air had certainly the most beneficial effect on the infant, especially when the mouth-to-mouth breathing was combined with the raising and depressing the arms.

Pyuria in Little Children (Dr. R. C. R. Jordan: quoted from *Journal für Kinderkrankheiten*, Hefte iii.–iv., 1872).—The passage of pus with the urine of little children is not an uncommon thing, according to observations made in the children's hospitals of Birmingham. However, the author has never found a single case of idiopathic cystitis, so that the occurrence of the disease at the age of early childhood appears doubtful. He is of the opinion that the occurrence of pus in the above-named cases depends upon some obstruction preventing a free passage of urine, or from the local irritation of the bladder produced by the presence of a foreign body. In each of these instances a certain amount of urine will be retained, and become ammoniacal, thus inducing and keeping up the irritation. The ordinary causes are divided by the author into two classes: 1. An internal cause, viz., stone in the bladder or kidneys. 2. External causes—as congenital phymosis, hypospadiasis, etc. Rarely some cases may come under another head, as deposit of tubercles in the kidneys. If now any of these hinderances are present, distention of the bladder is produced, and when the cause of obstruction cannot be overcome, pus is formed by the irritation caused by the decomposition of the urine. A further result is the dilatation of the ureters, and at last cystic degeneration of the kidneys, with formation of abscess, and death.

TRACHEOTOMY IN PRIMITIVE CROUP (*Journal für Kinderkrankheiten*, July and August, 1872; quoted from *Clinical Gazette* of Palermo.)—The journal alludes to the fact that this operation has never been approved of heartily in Italy, because the operation is performed too late, as a last resort after the glottis has become narrowed, and after innervation of the trachea has been impaired,—in fact, after asphyxia has commenced.

MISCELLANY.

BOSTON DISPENSARY FOR SKIN-DISEASES.—The first annual report of this institution, recently published, contains much of interest pertaining to this subject. The report of the physician in charge, Dr. Edward Wigglesworth, a gentleman well known in connection with dermatology, shows that there were over eight hundred cases of skin-disease recorded for the year, constituting probably the largest clinic of the kind in our country. The report gives many varieties of cutaneous disease, and among the commoner affections we note, in the order of their frequency, eczema, acne, dermato-syphilis, psoriasis, and seborrhœa. There were but ten examples of scabies, while the vegetable parasitic diseases were also remarkably few in number. With the establishment and success of institutions in our large cities for the study and treatment of this class of diseases, dermatology is rapidly taking its place as one of the important specialties of medicine, and is as such obtaining the recognition which it rightly deserves. The institution just referred to, with Prof. Agassiz at its head, is a credit to our country at large.

THE following is an abstract of a table of medical societies in the United States, reported by Dr. J. M. Toner, of Washington, D.C., to the American Medical Association:

Total number of Medical Societies	405
Number of National Medical Societies	5
Number of Medical Societies in	
Alabama	20
Arkansas	7
California	13
Colorado Territory	2
Connecticut	11
Delaware	1
District of Columbia	4
Georgia	4
Illinois	29
Indiana	12
Iowa	10
Kansas	4
Kentucky	8
Louisiana	1
Maine	5
Maryland	4
Massachusetts	11
Michigan	14
Minnesota	4
Mississippi	3
Missouri	5
Nebraska	3
New Hampshire	2
New Jersey	23
New York	90
North Carolina	1
Ohio	15
Oregon	3
Pennsylvania	49
Rhode Island	2
South Carolina	4
Tennessee	2
Texas	5
Vermont	8
Virginia	11
West Virginia	3
Wisconsin	7
Total	405
Number of societies reporting number of members	360
Total number of active members reported	20,662
Total number of honorary and corresponding members reported	1,970
Total membership	22,632

THE GERMAN SURGICAL CONGRESS.—The second annual meeting of the Society of German Surgeons commenced on the 16th of April, when the members assembled in the hall of the University of Berlin, under the presidency of Herr von Langenbeck. A large number of the most eminent German surgeons were present, including, *inter alios*, Bardeleben, Baum, Billroth, Busch, Esmarch, Hueter, König, G. Simon, Textor, Volkmann, etc. Visitors from England, Russia, and Belgium, also assisted, Mr. Spencer Wells being among the number. Drs. Volkmann and Gurlt were appointed secretaries, and Dr. Trendelenburg treasurer. The scientific business was commenced with an address by Dr. Billroth, on the "Extirpation through the Neck of Large Cancers of the Tongue seated far back." This was followed by a paper by Dr. Busch, of Bonn, on "Wounds inflicted by the Chassepot Rifle at Short Distances." A large number of the members and visitors afterwards dined together.

As indicating the growing attention the subject of hygiene is receiving, not only from the public but from the medical profession, we are glad to see that *The Practitioner* (Macmillan & Co., London and New York) is to be enlarged by the addition of a department devoted to Public Health. The forthcoming number will contain, under this head, articles on Sanitary Organization in England; the Health Aspects of Sewage Irrigation; the Propagation of Typhoid Fever by Milk; International Hygiene in Relation to Plague and Cholera.

BARON ADOLPH DE ROTHSCHILD has founded and endowed a hospital for diseases of the eye, at Geneva, at an expense of £20,000, which is wholly borne by himself. Dr. Barde, of Geneva, is appointed medical officer to the hospital.

AN ITALIAN OVATION TO VIRCHOW.—The *Racoglitore Medico* lately appealed to Italian physicians to honor Virchow with a medal for his prosecution of studies in the manner adopted by Morgagni. The appeal was promptly answered, and the medal was presented to the German consul in Rome for delivery. The medal is one of the finest preparations of the celebrated Florentine artist Gori, exhibiting upon one side a finely executed image of Virchow, and on the other the inscription "A Rudolfo Virchow, dalla patria di Morgagni i medici Italiani MDCCCLXXIII."

"BABY-FARMING" IN WASHINGTON, D.C.—It has recently been discovered by the authorities that a female physician in Washington keeps a private lying-in hospital, the children born in which are "farmed out" to colored women. Two of the children were found at a filthy tenement-house in a street bearing the name of "Hog Alley." The keeper of the "hospital" does not claim to have had a regular professional education; she says she has reported the cases of midwifery under her charge to the Board of Health, but with fictitious names.

THE St. Louis *Democrat* is responsible for the following semi-professional obituary doggerel:

"Our little Sally did to heaven go,
Baby life so fleet is;
She was a victim to the cerebro-
Spinal meningitis."

TRICKS OF A "TRICK DOCTOR."—The *Washington Star* of May 3 contained the following:

"Several weeks ago a healthy-looking colored man was seized with illness and took to his bed. A physician (a regular practitioner) found that the case was an obstinate one, and the patient gradually became worse under his hands. Some of the sick man's friends insisted that it was the duty of the wife to secure the services of a 'trick doctor' or conjurer, who could ascertain what was the matter with him, and remove the 'spell' if any had been put on him. By her consent a 'trick doctor' was brought to the house. On his arrival he said that there were two ground puppies (whatever they are) in the patient's stomach. To determine to a certainty whether there was no puppy, one puppy, or two puppies in his stomach, the conjurer procured two small china dolls, and turning down the bedclothes he set them on the sick man's stomach, with their faces towards his, and ordered quiet in the room, saying that if they both fell off there were no puppies in the sufferer, and he would have to make another 'speriment; that if one fell off and the other remained on him, there was one ground puppy in him, and if in falling they bumped their china heads together, then 'there were two ground puppies in him, sure.' The friends around the bedside kept very quiet, and watched the motions of the china dolls with great interest, as they rose and fell with the movements of the sick man's chest, and when, in a few moments, the dolls made a pitch forward, bumping their heads together, there was a heavy sigh from the bystanders, with exclamations of 'Look dar, now!'

"The trick doctor, having by this ''speriment' satisfied nearly all present that there were puppies in the man, then tried the further ''speriment' of making a bargain with the wife for pay; but in this he was unsuccessful, she declining to pawn her husband's watch for this purpose, or to sell the furniture, and the 'doctor' retired without a fee. During the following night the patient died, and the wife determined to prove that there were neither puppies nor poison about. Accordingly she requested the regular physician who had attended her husband to make a post-mortem examination, and accordingly one was made. The cause of death was found to be a tumor of the liver."

A DENTIST FINED FOR GIVING CHLOROFORM (*The Clinic;* from the *France Médicale*, April 23, 1873).—M. Debaralle, dentist at Lille, was brought up before the *audience correctionelle* for having given chloroform without the diploma of doctor in medicine or officer of health, and for having through "*imprudence, négligence, maladresse et inobservation des règlements*" committed an involuntary homicide by chloroform upon the person of a woman named Caron.

The tribune decided that the administration of chloroform without a diploma was an illegal practice of medicine, and that the defendant was guilty of homicide. As he was guilty of two offences, he was fined 15 francs for the first, and for the second 500 francs, with imprisonment for one month.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 20, 1873, TO MAY 26, 1873, INCLUSIVE.

FRYER, B. E., SURGEON.—When relieved by Assistant-Surgeon Moffatt, to comply with orders received from War Department. S. O. 42, District of New Mexico, May 15, 1873.

FRANTZ, J. H., SURGEON.—Granted leave of absence for sixty days. S. O. 27, Military Division of the South, May 20, 1873.

WEEDS, J. F., SURGEON.—Assigned to duty as Post Surgeon at Fort Randall, Dakota Territory. S. O. 103, Department of Dakota, May 17, 1873.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Cronkhite, to comply with orders received from War Department. S. O. 96, Department of the South, May 17, 1873.

CRONKHITE, H. M., ASSISTANT-SURGEON.—Assigned to duty at Oglethorpe Barracks, Savannah, Georgia. S. O. 96, c. s., Department of the South.

MOFFATT, P., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Union, New Mexico. S. O. 42, c. s., District of New Mexico.

STYER, CHARLES, ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 101, A. G. O., May 19, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF HYDROTHORAX IN WHICH PARACENTESIS WAS PERFORMED.

Delivered at the Philadelphia Hospital, May 31, 1873.

BY WILLIAM PEPPER, M.D.

GENTLEMEN,—The patient to whom I ask your attention this morning has already demanded our careful study on account of the interesting and complicated symptoms he has presented. You will remember that the most important of these were profuse vomiting of blood, with ascites and large serous effusion in the right pleural cavity. But in order to bring the features of the case clearly before you I will briefly review its history, so far as I have been able to learn it.

William E., a shoemaker, aged 71 years, was admitted to the Medical Wards of the Philadelphia Hospital on March 25, 1873. He has led a regular and rather sober life, and enjoyed general good health. In 1845 he had a long spell of subacute rheumatism, and since then his heart has been at times troublesome, fluttering and palpitating; but he has had no cough or œdema of the feet. For one or two years past his urine has been heavily charged with urates, and he has been obliged to rise once or twice at night to void it. His digestion has been uniformly good until the past six or eight months, since when he has had a great deal of gastric uneasiness with sense of fulness and oppression after eating, and with eructations, but with little nausea or actual pain, and no vomiting. The action of the bowels has been very variable, either constipated or loose, and at times the ingesta have seemed to pass very soon, and almost unchanged. About the first of the present year, he noticed the abdomen enlarging, and since then he has been weaker, and his breathing has been more oppressed after exertion. On the night of March 20 he went to bed feeling as usual, but waked about midnight with a feeling of oppression at the epigastrium, and immediately vomited a large quantity of blood. The amount is represented as having been several quarts. This is in all probability an exaggeration; but at any rate the loss of blood was large enough to cause a dangerous state of exhaustion with almost complete loss of consciousness, from which he was but slowly recovering at the time of his admission, five days later. The hæmatemesis did not recur, but for several days afterwards there were black, tarry stools, evidently composed largely of altered blood.

On admission he presented an appearance of extreme anæmia, with a bloodless countenance, and blanched mucous membranes. His mind was dull and listless, with alarming exhaustion of strength. There was complete anorexia, with an excessively dry and brown tongue. The heart's action was frequent, feeble, and very irregular, but no valvular murmur was detected. The abdomen was distended, and contained a considerable amount of effusion. There were also positive evidences of an effusion into the right pleural cavity extending up to the level of the second intercostal space. The urine was free from albumen, and the deposit presented no evidence of kidney disease.

He was ordered a diet of milk and beef-tea given in small quantities, at short intervals, and in part administered by enema. He also took fifteen drops of oil of turpentine in emulsion, every three hours. By the 10th of April, the tongue having become cleaner and moist, with some return of appetite and power to digest food, while the effusion in the chest and abdomen were increasing, the turpentine was omitted, and he was ordered

℞ Pulv. scillæ, gr. j;
Pulv. digitalis, gr. ½;
Potassæ nitratis, gr. iij.
Ft. pil.
S.—Every third hour.

Under the action of this, the pulsations of the heart became much more slow and regular, so that the digitalis was omitted after the fourth day of its use. For some days there seemed to be a diminution in the serous effusions, but this was followed by increase both of the ascites and hydrothorax. There were habitually several serous stools in each twenty-four hours, usually at night, and the irritability of the bowels was so great as to render the use of even the mildest purgative inexpedient. Various changes were made in the diuretics employed, but without any good result.

Before detailing the subsequent treatment of the case, let us consider the diagnosis, and try to learn the most probable explanation of the complicated morbid phenomena present. The most prominent of these is unquestionably the vomiting of blood, which proved so nearly fatal about six weeks ago; and it is well to determine its cause first. The conditions of the stomach in which hæmatemesis occurs are not numerous. Occasionally it appears as a substitute for some bloody discharge which has been arrested; but I believe this is limited to women, in whom a process of vicarious menstruation may take place from the gastric mucous membrane. But apart from this, and the acute specific fevers in which vomiting of blood may occur, it usually depends on either cancer of the stomach, or gastric ulcer, or intense congestion of the mucous membrane. We may safely assume that there is no cancer of the stomach in the present case. The patient, it is true, has had dyspeptic symptoms for the past year, but there has been no progressive emaciation, and no cachectic or anæmic appearance until the occurrence of the late hemorrhage; there has been no epigastric pain nor tenderness, no vomiting, and examination reveals no tumor in the region of the pylorus. Again, the hæmatemesis which attends gastric cancer is usually small in amount; the blood oozes gradually from the diseased mucous membrane, mixes with the contents of the stomach, is acted upon by the gastric juice, and is finally vomited in the form of blackish particles mixed with altered food. It is comparatively rare for vomiting of pure unmixed blood to occur in cancer of the stomach, and extremely rare for the amount of blood so vomited to approach that which was lost in the present case.

Again, the idea of ulcer is discountenanced by the age and sex of the patient,—for ulcer of the stomach is much more common in early life and in women,—

and by the same absence of pain and tenderness and vomiting, all of which are its very constant attendants. It is true that sudden and very profuse vomiting of blood sometimes occurs in cases of perforating gastric ulcer; but the entire absence of the usual concomitant symptoms prevents us from accepting this interpretation of the present case. It must further be remembered that, upon the supposition of either cancer or ulcer, no explanation would be afforded of the ascites and hydrothorax, whereas it is in the highest degree probable that these conditions and the gastric hemorrhage are due to a common cause. The remaining condition to which I alluded as a possible cause of this hemorrhage was congestion of the mucous membrane of the stomach,—a state which occurs in a good many diseases, and which I am satisfied does not receive the attention it merits, either in a diagnostic or therapeutic sense. But it is only when this congestion depends upon a mechanical obstructive cause that it becomes sufficiently intense to cause the rupture of minute blood-vessels of the mucous membrane, and actual hemorrhage. It is possible that this may take place in some of the forms of obstructive heart disease, but as a matter of clinical observation it is chiefly in connection with cirrhosis of the liver that gastric hemorrhage from intense congestion occurs.

The explanation of such a connection is clear enough. The process of cirrhosis, attended at first with hyperplasia of the interlobular connective tissue which invests all the minute blood-vessels, and subsequently with contraction and induration of the entire organ, as these swollen tracts of connective tissue undergo change into dense fibroid bands, is associated from first to last with obstruction to the portal circulation, which increases until it becomes so intense that some relief must be afforded to the engorged veins which form the radicles of this great venous system. We see the first effects of this engorgement in the disturbed functions of the various abdominal organs. Digestion is impaired; there is a sense of fulness and oppression at the epigastrium, with eructations of gas or acid fluid, and occasional nausea and even vomiting (though this latter symptom is far from common), all of them evidences of the chronic gastric congestion and catarrh. The action of the intestines is irregular, torpor and constipation alternating with catarrhal diarrhœa, while the appearance of hemorrhoids attests the congestion of the lower bowel. The kidneys are engorged, and the urine, variable in amount, is usually heightened in color and loaded with urates. Later the increasing congestion produces even more serious results. Serous diarrhœa becomes habitual, or more commonly the serous effusion takes place from the surface of the peritoneum, and ascites is developed; and at last, particularly if there is any weakening of the vessels, as often occurs in advanced life, there are ruptures of the over-distended capillaries, with more or less profuse hemorrhage from the bowels or into the stomach, exciting hæmatemesis. So often indeed do these latter symptoms present themselves in the later stages of cirrhosis of the liver, that I enjoin upon you the great importance of suspecting and examining for the presence of that condition in every case of gastric or intestinal hemorrhage. You will see at a glance how completely the development of the case we are now studying together has corresponded with the hasty sketch I have given you of the symptoms of cirrhosis of the liver. You will see how well the diagnosis that our patient is suffering with that disease accords with his age, with the gradual appearance and characters of his gastric and intestinal dyspepsia, with the absence of severe pain, tenderness, tumor, or frequent vomiting, and with the presence of ascites, and ultimately of hæmatemesis. I have, therefore, no hesitation in deciding positively upon that view of his case. There is, however, one very important condition in regard to which you may naturally ask for further explanation. It is the large effusion which, as I before stated, was found in the right pleural cavity, and which can have no direct connection with the condition of the liver, since the pleural veins empty, by the azygos and superior intercostal veins, into the superior vena cava. There is, indeed, no little difficulty in explaining this part of the case, because the effusion is altogether limited to the right side. This might readily be accounted for if it were the result of inflammation of the pleura; but the entire absence of pain or febrile action during its development is opposed to this idea, and leads me to conclude that it is of the nature of a pure passive dropsy. There is no reason whatever for believing that the kidneys are seriously implicated in this case. The heart, although its action is very irregular, is the seat of no obstructive valvular lesion which could account for the development of this hydrothorax. We must, therefore, look for its explanation to the general conditions associated with the cirrhosis of the liver. And, in the first place, it must be remembered that no such extreme vascular obstruction as attends advanced cirrhosis can possibly occur without inducing a tendency to general venous stasis. Add to this that, in the present case, many influences have favored the development of a marked degree of anæmia, which strongly predisposes to serous effusion. And finally it is very generally found that, in cases of cirrhosis of the liver (especially, as it has seemed to me, when this comes on independently of alcoholism, as a form of senile degenerative fibroid change), there are alterations in the serous membranes and capsules of the solid organs throughout the body. It may well be, therefore, that in the present case slow changes have been occurring in the pleura which have favored the production of serous effusion there. It is clear that some, or all together, of these causes have led to the extensive hydrothorax which was found in our patient's right chest. But still it is not so clear why the effusion should have been limited to the *right* side, since all of the causes above mentioned would favor with equal force an effusion into the left side, and it appears scarcely reasonable to conclude that, while they led to the development of an enormous serous effusion on the right side, the left pleural cavity should remain entirely free. The only explanation of this which I can suggest is to be found in the special conditions of the lungs and

heart which I believe to be present; and on this account I have reserved the following results of their more careful examination until this time.

(To be continued.)

ORIGINAL COMMUNICATIONS.

EXCISION OF THE HIP-JOINT SUCCESSFULLY PERFORMED.

BY G. TROUP MAXWELL, M.D.,
New Castle, Delaware.

ON the 14th of November, 1872, I excised the hip-joint of Thomas Buckworth, at his father's home in Cecil County, Maryland.

Mr. Buckworth had labored under coxalgia, or tuberculosis of his right hip-joint, eighteen years. He was, at the time I operated, thirty-five years old, and the disease appeared when he was seventeen years of age. During that time, or from the sixth month after the first symptom of the disease —pain in right knee—showed itself, with a few short intervals, pus issued from orifices, or vents, it made for its escape, in the upper portion of the thigh. Several small pieces of bone had, at different times, made their exit also from the same openings. There had been, in all, six outlets for the bone and pus, but never more than two were in active eruption at the same time, some closing, as the pus would make other places of escape for itself. The limb was shortened about three inches, which caused a decided limping gait, and the discharge and long-continued irritation were gradually but surely undermining the patient's strength and health. Indeed, labor was impossible, and life had become a burden. As, notwithstanding the long continuance of this exhausting disease, there was evidence of considerable physical stamina and recuperative energy remaining, I deemed it proper and safe to excise the joint, and, accordingly, recommended the operation.

After sufficient preliminary and preparatory medical treatment and regimen, the operation was done on the day above mentioned.

I had the valuable assistance of Drs. W. H. Barr and Robert McKee, of Middletown, Delaware, on the occasion; and without much difficulty, the patient being profoundly under the influence of chloroform, the entire head of the femur and a considerable portion of the upper part of the rim of the acetabulum were removed.

As there was nothing remarkable about the mode of procedure, a detailed account of the operation is unnecessary. Believing that the greatest difficulties in most operations are overcome with increased facility when the external incisions are large, I first made a semi-lunar incision, with the convexity downwards, then a straight incision of four inches down the thigh, connected with the first at the point of its greatest convexity.

To wash out the wound I used a solution of carbolic acid,—two drachms to the quart of water,—and during the after-treatment a cloth wet with a stronger solution of the acid was kept constantly over the wound.

The patient came from under the influence of chloroform in a short time after the operation was concluded and the wound dressed, and evinced very little sign of shock. Not only did he enjoy almost entire exemption from depression of the nervous system immediately consequent upon the operation, but, what was equally surprising and gratifying to me, there was almost complete immunity from febrile reaction. His progress towards recovery was rapid and continuous until the twenty-fifth day. The purulent discharge was, of course, abundant during the first week; but it then steadily diminished, the wound healing rapidly at the same time. His spirits, appetite, and digestion were also in excellent condition. At the end of the fourth week, however, the whole appearance of the case changed suddenly. The discharge ceased wholly, the wound assumed a glazed, unhealthy look, and the parts about the joints were hot, red, and much swollen. In addition there was complete anorexia, —food being loathsome to the patient; and, withal, for the first time he lost spirits, and became despondent. Discovering the true nature of the complication and cause of the radical change in my patient to be malarial poisoning, he was quickly relieved by the administration of a few doses of quinine, and at the end of the fifth week his case had resumed its previous cheerful aspect. By the end of the seventh week the wound was healed perfectly, and the patient was walking about his room by the aid of a single crutch at the close of the ninth week.

The success of the operation is, therefore, absolute, as now—at the end of six months—he has a comparatively useful limb, shortened slightly, but with a little motion in the joint, and fitting him for employment in many vocations.

I have been succinct in the account of this case, as there was not anything peculiar about it, and the only purpose I have to subserve in its publication is to offer the encouragement which a successful operation may afford to the profession.

MAY 27, 1873.

BATRACHIAN METAMORPHOSIS WITHIN THE OVUM (*British Med. Journal*, May 3).—M. Jules Garnier, the explorer of New Caledonia, makes known through the *Revue Scientifique* an observation of M. Davay, *pharmacien* in Guadaloupe. It is to the effect that in the country there is a frog—the *Hylodes martinicensis*—which does not undergo the ordinary tadpole transformation, but is fully formed *in ovo*. On examining an ovum taken from the gelatinous mass in which they lie embedded under moist leaves, there is found a slender embryo with a large head, four styliform limbs, and a tail folded in. On touching the egg, the embryo changes its place. A day later, the embryo has a tail as long as its body, translucent and flat, like a tadpole's tail. The limbs then become developed, and some days later the little frogs escape, being of a deep brown-gray color, and not presenting the least vestige of a tail.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 7, 1873.

EDITORIAL.

THE SOCIAL EVIL.

AFTER all the discussion which has taken place in England with regard to the advantages and disadvantages of the Contagious Diseases Acts, it seems as if the question was practically settled by the results set forth in the official returns for the year 1872. We quote from the *Lancet* for May 10 the following statements, which, in our opinion, are worth volumes of theoretical opposition :

"It (the report) states that the women in the several places subject to the Acts attended with regularity throughout the year, and that in a few instances only was it necessary to take proceedings before a magistrate. The Acts have exercised a repressive influence in several ways. Notwithstanding, we are told, the continued influx of common women from unprotected districts, the total number in the several districts on the 31st of December last had been reduced. The beneficial working of the Acts is, however, more clearly demonstrated by the reduction in the number of juvenile prostitutes; and this is very striking. The number of prostitutes in the different districts under the age of seventeen on the 31st of December last was nine; whereas in 1866, when the Acts were first put in force, there were three hundred and seventy-seven under that age. Again, on the 31st of December last, those under the age of eighteen were sixty-seven; whereas in 1866 there were five hundred and ninety-five! The number of brothels has been reduced by eighty-six during the past year, many of those suppressed being of the lowest description: seventy-one young creatures between the ages of twelve and seventeen, and one hundred and thirty-five women between the ages of seventeen and thirty-one, who were known to have commenced immoral practices, gave up that course of life upon being spoken to by the police; and the Assistant-Commissioner's Report contains individual instances of many girls and married women who owe their rescue from a life of sin and misery to the well-directed and humane efforts of the officials engaged under these Acts."

In dealing with matters of this kind, the great point is to attack them where they are most vulnerable. We may not be able to get hold of the thread at the very end and trace it all the way through, untangling every knot, but if we can make a decided beginning,—as seems by the above showing to have been done in this instance,—the result may be even beyond our expectations. The main difficulty is, that the male sinners, to gratify whose passions the "social evil" exists, are not affected either by legal enactments or by social proscription. All they have to steer clear of is disease. But we do believe that it is far better to lessen the rampant luxuriance of vice, even if the measures must be partial, than to leave it unchecked. The way may open to still further reformatory proceedings. So far as we know, St. Louis is the only American city in which any attempt has been made to establish and enforce any systematic supervision of prostitutes by the police. We should like to learn what results have attended that experiment.

SANITARY MATTERS.

WE feel constrained to utter a note of warning, on the approach of another summer season, as to the inefficient protection afforded to the population of this city against the dangers which the hot weather brings with it.

Philadelphia was once known as the cleanliest of American cities. She showed to visitors, with much pride, her arrangements for an abundant supply of pure water. At the present time her streets are ill paved, dirty, and foul-smelling, and on the very threshold of the summer there is not a sufficiency of water, in the centre of the city, even for ordinary purposes.

With the mere matter of paving we are not now concerned; although badly-laid streets, where surface-draining is employed to so great an extent as here, are apt to become depots of stagnant water charged with unwholesome substances. We do most earnestly protest, however, against the whole system, or want of system, upon which some of the tax-payers' money is supposed to be laid out in a

pretence of keeping the streets clean. The shallowness of the pretence may be gauged in wet weather by the depth of the mud, in dry weather by the quantity of dust which every breeze brings to our nostrils. A law exists, but is in many neighborhoods a dead letter, against the throwing of kitchen offal into the streets. Everywhere the carcases of animals are seen scattered about, awaiting the chemical decomposition which is not only more certain, but more speedy, than the operations of the paid scavenger.

Bad as all this is, it is not so bad as the lack of water. With two great rivers flowing past, our citizens ought to have an absolutely unlimited use of this indispensable means of health and purity. And yet, year by year, every summer, the authorities are obliged to caution the public that there is danger of a water-famine. Let us imagine for a moment this state of things existing, and either a pestilence or a great fire breaking out. Is it necessary for us to hesitate in answering the question whether it would be better to spend a million or more in enlarging our mains, in providing more powerful pumping apparatus, or in arranging for some other source of water-supply,—or to let it go in the shape of lives destroyed by disease, or property reduced to ashes?

These are matters which will sooner or later force themselves upon the notice of the people. Better, far better, would it be to act promptly, to use the ounce of prevention, to "foresee the evil," as the wise man says, than to "pass on and be punished." A community, like an individual, may disregard the laws of hygiene, and live either in ignorance, recklessness, or defiance of them; but the time will come when the folly of such a course will be made unmistakably manifest.

CORRESPONDENCE.

To the Editor of the Philadelphia Medical Times.

DEAR SIR: Will you allow a stranger much interested in insurance matters to say a few words in regard to the interesting article on that subject in your number of May 17? While agreeing entirely with all that is said concerning the necessity for a thorough preliminary medical examination, and for an efficient and *entirely independent* body of medical examiners, I cannot admit that the only questions which should be raised, when a death-claim is presented, are those of identity and death, and that no misstatements in the application and no subsequent violation of the terms of the policy should be held to bar the claim.

There certainly appears no good reason why a life-insurance contract should not be treated as all other contracts are treated, and be liable to be set aside for fraud in obtaining it, or for the non-fulfilment of its conditions. If a man induces me to insure his dwelling-house, stating that the building is used as a dwelling-house only, and it appears afterwards that at that time he had petroleum stored in his cellar, surely no one holds that the *fire* policy is valid. Or if he puts the petroleum in the building after obtaining the policy, and contrary to its express stipulations, every one admits that the insurance is forfeited. Why should not the same rule apply where a *life* policy has been obtained by the concealment of some important fact or where some essential condition of good health and long life has been afterwards deliberately violated? Surely every company has a right to decide the conditions upon which it will make new contracts, and those who accept these contracts should not complain if the conditions are enforced. But the author of the article in question appears to go further, and implies that policies should not be so worded as to admit of this defence; that no such conditions should be imposed. This would oblige the companies to say to all comers, in effect, that if a rogue can only be cunning enough to escape the detection of his fraud on the preliminary examination, he need fear no future dispute of his claim, no matter what further information may subsequently be gained, or may be developed by the circumstances of the death. Is any other business conducted on such principles? Could it be safely? Does any merchant so regulate his private contracts? If so, why do we maintain courts of equity? If not, why should life-insurance companies alone among business associations be debarred from the relief those courts afford?

It must be remembered, too, that no preliminary examination, however careful, can elicit all the important facts of the applicant's condition. This business, like all others, has to be conducted largely upon faith in the statements submitted to us; and, as is done in every other business, the party making such statements should be held bound by them, and not the less because the real facts of the case are often, from their very nature, only to be discovered when death occurs.

It will be noticed that I do not here discuss the case when misstatements have been honestly made and with no intent to deceive any one. Neither do I wish to be understood as advocating or justifying the contesting of a claim on merely technical grounds. This, which is wrong in any business, is peculiarly so in life-insurance. But such cases are much less frequent than the public generally suppose. No one not familiar with the subject has any idea of the number of absolutely fraudulent claims presented to our insurance companies, or of the very large number of losses paid every year upon lives which never should have been insured, and which it is a moral certainty, though perhaps not to be proved legally, never would have been insured had the parties told the truth in their applications. So far from the companies being unduly anxious to contest such claims, it is certain that the managers of many of the mutual companies have incurred a very grave re-

sponsibility by the readiness, to use no harsher word, with which they have settled, without dispute, all sorts of losses, thus spending the money of their honest and truthful members in *charity* (for when no real right to the money existed, its payment could be nothing else) to the fraudulent or unworthy. For it must always be remembered, in regard to all these matters, that a mutual company is only an association of insured lives, and the fraudulent loss of the company is the loss of each individual member.

M.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, May 14, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. HENRY MARCH in the chair.

(Continued from page 556.)

ETIOLOGY OF BRIGHT'S DISEASE.

DR. F. C. CURTIS addressed the Society upon this interesting subject, and said:

It has been a subject of remark at post-mortem examinations that we very seldom see a perfectly healthy kidney. Although the same might be said of other organs, still it is true that Bright's disease is comparatively common.

The following case is peculiar only in regard to its etiology. Mr. L., the patient, was about 45 years old, a native of Canada, and by occupation a cooper; he had not, however, pursued his trade actively for some years, but had led an easy life. He has always been healthy, and his family history is good. He was of light complexion and of sanguineo-nervous temperament. There is no evidence that he has ever been of scrofulous habit; neither has he been intemperate in the use of stimulants. He asserted that he had always been perfectly healthy, excepting that he had had occasional attacks of sick headache, which were, as described, in no way peculiar. Aside from these he had no nausea or headache, his eyesight was normal, and he had no œdema. Prior to January last, the closest cross-questioning failed to detect any symptoms of disease of the kidneys, he being questioned with particular care, because he was under an accident insurance policy.

Early in January, while walking in the street, he slipped on the ice and fell, striking on his back and the back of his head, hurting no particular part, but causing a general jarring of the body. He states that he was unconscious for a little time, after which he had severe pain in the head, which persisted. He also vomited several times in the course of the morning. The fall did not, however, disable him so but that he was able to proceed directly to his business then in hand, which was of a pressing nature. He rode down town in an omnibus, walked to the lawyer's office, a short distance, and, after lying down for an hour or so, attended to the business, and then rode home as he came. His headache continued, and he vomited a few times, but was able to attend a trustees' meeting of his church in the evening from 7½ till 9 o'clock, though feeling badly. The headache persisted for three or four days, and his face was bloated.

On the third or fourth day his urine was noticed to be high-colored, and examination of it shortly after showed it to be highly albuminous. Occasional vomiting continued for a week or two, coming on especially when the head ached. About two weeks after the fall the lower limbs began to be œdematous. I saw him for the first time about the 1st of March; he then had no œdema of the face, nor did his face present the peculiar pallor of Bright's disease. He had some dyspnœa, but no cause for this could be ascertained, as his heart and lungs were healthy, and there was no peritoneal or pleuritic effusion. His general condition was fair, and he was able to be about the house. There was no disturbance of vision or other nervous symptom. His legs were œdematous. What his treatment was it is impossible to say, as he was under a homœopathic practitioner. I examined his urine at this time, six or seven weeks after his fall, with the following result: Color cherry-red; transparent, no precipitate; specific gravity 1022; albumen, I should say about five-sixths, as the test-tube was solid with it. Microscopically there was found renal epithelium, blood-globules abundant, blood, epithelial and granular casts. It seemed pretty clear from the examination that the disease was acute and of short duration, rather than that it had been running a latent course, now for the first time developing. The prognosis given at this time was that there was a possibility of recovery. The proportion of recoveries given by Frerichs from acute Bright's disease is two-thirds of those attacked, and Roberts thinks this below the average if cases resulting from scarlatina are included.

But the second examination of the urine, made three weeks later, seemed to settle the question of prognosis. The result of this was as follows: Urine a reddish color, opaque; reaction acid; specific gravity 1025; albumen three-fourths. Microscopically, blood-globules, renal epithelium—some of which was fatty—casts, which were abundant, were bloody, epithelial, hyaline, and fatty.

Evidently from this, the kidneys were passing beyond simple congestion and catarrh of the renal tubes. Here, within ten weeks of the onset, we see that there was fatty degeneration of the kidneys, with waxy casts, indicating chronic disease. According to the view of Frerichs, Niemeyer, and the German pathologists generally, that the different anatomical changes of the kidney are only stages of one disease, the kidneys in this case had passed from the first into the second stage. Whether or not this unity of the forms of Bright's disease be a correct pathology, this case seems to illustrate its truth to a certain extent. That the contracted granular kidney is a third stage, ultimate to the large white kidney, is more difficult to prove. In fact, I believe it is the general experience that patients having the large white kidney are more apt to die. I have in mind two cases occurring side by side, in the New York Hospital, when I was a student; one believed to have the "large white kidney," his symptoms being great œdema of the limbs, which was not relieved, although the urine was passed freely under diuretics: the pallor was very marked, symptoms of nervous disturbance presented, and he finally died with convulsions and coma. Here all the prominent symptoms of the affection were very marked. The other was considered a case of "small contracted kidney." He had no pallor, and no symptoms of nervous disturbance from first to last; nor was there any œdema, the only effusion being into the peritoneum and subsequently into the pleural cavities. Under the use of tinct. ferri chlor. and an occasional purge, he finally began to improve, the kidneys and skin acted freely, so that the serous effusion disappeared entirely, albumen and casts cleared up from the urine, and to all appearance the man was cured, and was so discharged from the hospital. In these two cases, presenting symptoms ascribed to the two pathological conditions, we see the one dying in the second stage (so called), while the other, so far as could be seen, recovered. The second

case related, moreover, never passed through the symptoms of the second stage as seen in the first case. The theory of this unity of Bright's disease has been, perhaps, gaining ground with us because of the many translations of valuable German works, recently made, but I think the division into acute, smooth white, small granular, etc., separate diseases, held by Roberts, Dickinson, Wilks of Guy's Hospital, and others, has been the most commonly received here and in England. The possibility of a passage from a first to a second stage, illustrated by the case in hand, is not, that I know of, doubted.

After the second examination of the urine an unfavorable prognosis was given. The patient, however, at this time presented, clinically, an improved appearance. Later the œdema increased, the limbs, scrotum, and penis swelled; he failed steadily, and died without the occurrence of any symptoms of nervous disturbance, eighty-six days after the fall to which his death is attributed.

A post-mortem examination was made next day. The parts were found œdematous, as above mentioned. There was no effusion into the serous cavities. The lungs were healthy. The heart was somewhat enlarged, but the valves were normal and competent. Abdominal organs healthy, except the kidneys; these were much enlarged, white, smooth, and fatty. The capsule stripped up readily, leaving a smooth surface under it. The pyramids were partly destroyed. There were ecchymotic spots of small size in the left kidney. Microscopical examination showed abundance of fat in the tubes and fatty degeneration of the epithelium.

The termination of this disease fatally within three months of its alleged cause makes the etiology here especially important. Clearly, the man died of Bright's disease simply. Had this been running a latent course and developed at the time of, perhaps by, the injury? Hardly; for some symptoms of failing health must have been apparent, even though a diagnosis had been impossible. The urinalysis, too, shows pretty conclusively that the inflammation of the kidneys was a recent one. Both subjective and objective symptoms point to about the 1st of January as the probable time when the disease commenced.

The usual causes of Bright's disease are, exposure to cold, the use of alcoholics, and the influence of zymotic poisons, more especially scarlatina.

Minor causes are hereditary tendency or constitution of body, such as scrofula and tubercle, excessive use of such drugs as copaiba, turpentine, etc., pregnancy, and other conditions. All authorities are unanimous in giving these. Aitken alone alludes to certain causes which, to quote his words, "may be regarded as mechanical causes of irritation, but which so secondarily affect the constitution of a person predisposed to the disease, that Bright's disease, rather than any other, is the result,—*e.g.*, the irritation of blows, of cantharides or other irritants, the presence of calculi in the kidney, etc." In other words, in a person predisposed to this disease by climate, habit of life, or other condition, irritants, including traumatic injuries, may develop it. We cannot find in this case any predisposing cause: the accident occurred in steady winter weather, his occupation did not expose him to cold or moisture, his health was at its usual standard, and he had always been free from disease; his habits of life were in all respects temperate; the post-mortem showed his other organs to be healthy. In short, none of the ordinarily accepted causes, predisposing or exciting, can be found.

The question of causation seems then either to be limited to the fall, acting simply and alone to produce the disease, or else the case is one of those in which the most searching analysis fails to detect the cause. The possibility of the fall acting as a cause for Bright's disease, unless effecting traumatic injury to the kidney, may well be doubted. Could reflex action or injury to nerve-centres produce disease of the kidney? It does not appear improbable, but I do not know any direct authority for it. It is not easy to express opinion in matters so vague as such suppositions lead us to. I should be glad to hear the views and experiences of others in the matter.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 24, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. H. LENOX HODGE exhibited a *multilocular ovarian cyst* removed by ovariotomy on Saturday, April 12.

The tumor weighed fifty-five pounds, and consisted of many cysts, great and small. The fluid varied much in consistency, part of it being nearly as firm as jelly, and part of it quite limpid. The color also varied much, being, however, mostly dark. The tumor came from the left ovary, and had a pedicle about four inches in length. It was first noticed sixteen months ago. The patient is forty years of age, and had been tapped four times. The tumor was removed by ovariotomy twelve days ago, and thus far the patient has done very well.

Specimens of the fluid were submitted to Drs. BERTOLET and RICHARDSON for examination.

Dr. R. M. BERTOLET said he had examined the fluid from this tumor and had found the specific gravity 1014. Microscopically it contained free nuclei, granular matter, cholesterine crystals, and epithelial cells derived from the lining of the cyst-walls. Most of these cells had undergone fatty degeneration and disintegration. The so-called compound granule-cells were numerous, but presented nothing peculiar. He had seen similar cells in other fluids derived from the abdominal cavity. On the addition of acetic acid some of these exhibited a reaction similar to that of leucocytes, but the majority were much larger than pus-corpuscles. On the addition of ether the granules and globules disappeared. He thought it was quite impossible to base a diagnosis of ovarian tumor upon their presence.

Dr. JOSEPH G. RICHARDSON had also examined the fluid, but said he had very little to remark in addition to what had been stated by Dr. BERTOLET. He had, however, measured a number of these corpuscles, and found them to average $\frac{1}{100}$ of an inch in diameter, and to be generally stuffed with oil-globules of considerable size. He thought that their diagnostic value might lie in the fact that the flat endothelial cells would not be likely to become distended so as to assume a spherical shape. The globules of oil contained in them were sometimes very large, occasionally $\frac{1}{400}$ of an inch in diameter. In some of the cells in which the fatty degeneration was less advanced, he had been able to distinguish a cell-wall.

Dr. BERTOLET said that, as a rule, the corpuscles were without a cell-wall, and appeared to be merely an agglomeration of fat-granules.

Dr. RICHARDSON further remarked that in two or three cells he had been able to make out a nucleus. It was single, and of large size. He desired to know of Dr. BERTOLET whether he knew what was the thickness of these endothelial cells which line the cavities in fibro-cystic growths of the uterus, for example.

Dr. BERTOLET, in reply, said he had never taken the trouble to measure their thickness. Other forms of cells, columnar, even ciliated epithelium, had been found in ovarian fluid by Peaslee and others.

Dr. RICHARDSON said the point which he wished to

make was that these very flat endothelial cells of uterine cysts would not be likely to swell up so as to assume a spherical form by their fatty degeneration.

Dr. JAMES TYSON said that the compound granule-cells were not necessarily derived from the flat endothelial cells, but perhaps descended from the deeper layers of cells of spherical shape which physiologically impressed would become the flat endothelium, but pathologically impressed became compound granule-cells.

Dr. W. G. PORTER exhibited, for Dr. H. LENOX HODGE, *sections of femur and tibia, and the patella*, removed in the operation of *excision of the knee*, done this morning at the Presbyterian Hospital. The patient is a young man, twenty-six years of age. When a child of three years, he began to suffer with inflammation of the left knee, which has continued with more or less violence ever since. The limb had become much wasted and useless. He could not bear any weight upon it without suffering much pain. There was slight motion at the joint. The patella was firmly adherent to the femur by bony anchylosis. The femur and tibia were bound together by strong fibrous bands. In the left side of the head of tibia an abscess was found extending more than an inch in depth from the joint. As the section shows, only the articulating surface was removed. The position of the abscess was treated by the gouge.

Dr. J. SOLIS COHEN exhibited a *fragment of bone removed post-mortem from the larynx* of an adult male.

Dr. BERTOLET said this was a truly remarkable specimen, and he could easily see how it could be mistaken for a necrosed cricoid cartilage. Had the curve been turned the other way it could easily have been seen laryngoscopically, and extracted; but in its present situation extraction would have been impossible without laryngotomy.

He said it was a disputed question as to whether necrosed cartilages partially ossified should be removed. In this case an operation under the supposition that the foreign body was a necrosed cartilage would have been a fortunate one. Indeed, Dr. BERTOLET considers the operation at all times a proper one, since there is always more or less danger of the detached fragment falling into the trachea or becoming impacted in the glottic fissure.

The specimen was referred to Drs. HARRISON ALLEN and W. W. KEEN for examination. These gentlemen reported as follows:

"The committee to whom was referred the specimen of the larynx exhibited by Dr. J. Solis Cohen at the last meeting of the Society, have the honor to report that they found the specimen opened along its posterior wall,—the cricoid cartilage being divided at the median line. The cartilages were more or less ossified. The cut through the cricoid showed within this cartilage extensive bony change. The mucous membrane was everywhere intact, save at two points a little below the vocal cords, where ulcerative abrasions were seen, each about the size of a grain of barley.

"Accompanying the laryngeal specimen was a fragment of bone. The committee was informed that it had been found lying across the cavity of the larynx, and had maintained its position at the sites of the lesions already mentioned. The fragment resembled a portion of a bony ring. Its concave surface was smooth; its convex was somewhat roughened and marked by a central pit. One of the sides was rounded and even, another was uneven, and apparently eroded. The first-mentioned border was obliquely facetted. The facets were oblong, and had been at one time probably covered with cartilage. The fragment measured seven lines through its greatest length, and three lines through its greatest width. It resembled in its general outline a portion of the ossified cricoid cartilage. This structure, however, was in position and apparently unchanged by any loss of tissue.

"The committee were unable to identify the specimen with any portion of the skeleton of an animal which may have been partaken of by the patient with his food."

THURSDAY EVENING, MAY 8, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

CHRONIC ARTHRITIS OF THE KNEE.

Dr. H. LENOX HODGE exhibited *sections of the femur and tibia and the patella*, removed by the operation of excision of the knee, done nine days ago, at the Presbyterian Hospital. Thus far the patient has done well. He is eight years of age, and has suffered from inflammation of the knee for about three years. The knee was partially flexed, and retained limited movement. The child could not make use of it in walking, and suffered pain on pressure. On inner side of lower part of femur there was a scar of an old abscess. The internal condyle of the femur has a deep ulceration upon it, causing a large indentation. The rest of the articulating surfaces seem free from disease.

Dr. H. ALLEN suggested that in view of the position of the patch of ulceration—viz., at the side and near the front of the condyle—the disease had been located in the epiphysis, and not primarily in the joint.

Dr. JOHN H. PACKARD said that he thought, and that only a day or two ago his attention was called to the distinctly expressed opinion of a leading English surgeon, that when the patella was allowed to remain it often became the cause of further disease. He himself thought also that a limb in a very slightly flexed position was more available for walking than a straight one; that a patient with his leg in a straight line was in the condition of a man with the old-fashioned wooden leg.

Dr. ASHHURST asked whether the synovial membrane appeared diseased.

Dr. HODGE replied that over the internal condyle there was evidence of ulceration, extending even to the bone.

Dr. PACKARD remarked that, except where the peculiar construction of the joint, as in the shoulder and hip, would not permit it, he believed it to be the accepted rule to make a complete exsection rather than a partial one, so as to have two fresh bony surfaces opposed. In the ankle he thought the rule was also less important. With regard to the latter joint, he would like to know whether any one had had the opportunity to dissect this part after the operation of excision. He had in one instance excised the astragalus in a child, and in course of time its place seemed to become filled by a new formation.

Dr. ALLEN asked how the child walked after the astragalus was removed.

Dr. PACKARD replied that the child walks perfecly well. There is free motion and no tenderness whatever.

The PRESIDENT confirmed what Dr. Packard said with regard to loss of the astragalus, by the instance of a boy who came under his notice at the Pennsylvania Hospital, having lost this bone, and in whom there was subsequently no impairment of motion.

Dr. ALLEN remarked that the relations of the astragalus to the arch of the foot showed that the weight of the body is transmitted mainly along its axis. This understood, it becomes interesting to study the mechanism of progression after the removal of the astragalus. He thought it probable that the weight would in that event be thrown more upon the calcaneum, and the arch of the foot, if not destroyed, at least greatly impaired.

Dr. HODGE said that when the bone is discharged by disease, and the periosteum remains intact, regeneration may be expected to take place, and mentioned a case in which he removed two-thirds of the tibia in its whole thickness, and stated that the bone has been reformed and the limb is perfectly useful.

Dr. PACKARD referred to an old case of excision of the astragalus, by Dr. Levis, in which there is a depression, but the boy walks well.

Dr. DE F. WILLARD said he thought the malleoli might be thrown into a new position, rotating on their longitudinal axis so that the internal would move forward and the external backward, as seen in cases of club-foot of long standing in adults.

Dr. J. EWING MEARS presented a specimen of *follicular colitis*, taken from a child aged eight months. The patient manifested the symptoms which usually accompany this affection, convulsions finally supervening, which terminated in death.

Post-mortem examination revealed marked passive congestion of the brain, with serous effusion into the lateral and third ventricles. The stomach, liver, spleen, and small intestines were healthy. The only lesion found was that shown in the large intestine, which implicated principally the ascending and transverse portions.

REVIEWS AND BOOK NOTICES.

HANDBOOK FOR THE PHYSIOLOGICAL LABORATORY. By E. KLEIN, M.D., Asst. Prof. in the Pathological Laboratory of the Brown Institution, etc.; J. BURDON-SANDERSON, M.D., F.R.S., Prof. of Practical Physiology in University College, London, etc.; MICHAEL FOSTER, M.D., F.R.S., Fellow of, and Prælector of Physiology in, Trinity College, Cambridge; and T. LAUDER BRUNTON, M.D., D.Sc., Lecturer on Materia Medica in the Medical College of St. Bartholomew's Hospital, London. Edited by J. BURDON-SANDERSON, M.D. In two volumes 8vo. With one hundred and thirty-three Plates, containing three hundred and fifty-three Illustrations. Vol. i., Text. Vol. ii., Plates. Philadelphia, Lindsay & Blakiston, 1873.

No more useful aids to medical instruction have been supplied us in modern times than these volumes furnish. They are the first fruits of the new education, the object of which is to teach men to observe, think, and deduce, as well as to remember. We are told that the book is intended for beginners in physiological work, but we believe there are no teachers of physiology and histology in this country who would not teach with new enthusiasm by making it their guide. We believe, moreover, that there is no other book, in any language, so useful to teacher or student in the departments which it covers. For, in addition to the fact that there is no single work in the German which covers so extended a field, there is, even in those extant, a want of preciseness in the directions given which makes them unsatisfactory to beginners.

Part first, by Dr. Klein, is taken up with practical histology. The skill of Dr. Klein as a teacher of practical histology is well known to many Americans who have profited by it in Vienna and London, and these will hail with pleasure the extension of his usefulness which grows out of the issue of this book.

The subjects treated in part first are—the blood; epithelium and endothelium; connective tissues, including cornea, bone, and cartilage; muscular tissue; tissues of the nervous system, including the terminations of nerves; methods of preparation of the compound tissues, imbedding, section-cutting, etc.; the vascular system, including injections, structures of the blood-vessels, and microscopical study of the circulation; the lymphatic system; organs of respiration; organs of digestion, including the liver and spleen; the skin, cutaneous glands, and genito-urinary apparatus; organs of special sense; embryology, to which Dr. Klein has given much study, and on which he is an admitted authority; and, finally, the study of inflamed tissues, including inflammation of epithelium, endothelium, of cartilage, of bone, inflammatory changes in the liver-cells, in the cornea, in the tongue of the frog, and in the tadpole's tail.

Thus is covered the whole domain of practical histology, and throughout it the most accurate directions are given, so that if these are followed, with the assistance of the admirable plates, of which the only criticism that can be made is that they are not in the same volume with the text, one cannot go astray. To one who has had the advantages of Klein's personal instruction, reading the book seems like rehearsing with the master, so practical, so much to the point,—in fact, so like Klein does the text read.

The second part of the book, on Practical Physiology, is by Dr. Burdon-Sanderson. Those who have read his lectures on this subject in the *Medical Times and Gazette*, a year ago, will recognize much that was then published, and will be glad to have it in its present convenient form.

The subjects treated are—

1. THE BLOOD—*a*. the liquor sanguinis, or plasma; *b*. conditions affecting coagulation; *c*. the coloring-matter, its chemical properties, and the action of various agents upon it; *d*. gases of the blood, and methods of analysis.

2. THE CIRCULATION OF THE BLOOD, in which are described the kymograph, accessory apparatus and their uses; also the sphygmograph and experiments with the schema relating to the form of the arterial pulse. The functions of the vaso-motor nerves, with experiments illustrating them, occupy considerable space, and make this subject clearer than has heretofore been done. A complete study of the movements of the heart, with the influence of nerves and ganglia, and directions for the use of appropriate apparatus to illustrate the former, are contained in this chapter.

3. RESPIRATION is similarly treated in the next chapter; 4, ANIMAL HEAT, including thermometry, in the next.

The third part of the volume, also on physiology, is by Dr. Michael Foster, on the functions of muscle and nerve. An accurate description of special apparatus, more particularly electrical, is followed by a chapter on the general properties of muscle at rest; another on preliminary observations on the stimulation of nerve and muscle; a third on phenomena and laws of muscular contraction; a fourth on the wave of muscular contraction; a fifth on tetanus; a sixth on electric currents of muscles; a seventh on stimulation of nerves; an eighth on phenomena accompanying a nervous impulse; a ninth on various forms of stimulation of muscle and nerve; a tenth on urari poisoning and independent muscular irritability; an eleventh on the functions of the roots of spinal nerve, including recurrent sensibility; a twelfth on reflex action, and a thirteenth on some functions of certain parts of the encephalon.

Precise directions for experimentally showing all these points are laid down.

Practical physiology is continued in the remaining part, by Dr. Lauder Brunton, on digestion and secretion, with introductory chapters on the albuminous compounds and the chemistry of the tissues. In this are included albumen, its properties, and alterations

produced in it by acids and alkalies, a synopsis of albuminous compounds, including leucine and tyrosin, with their tests. The chemistry of the tissues includes that of nerve, muscle, connective tissues, etc. The chapter on digestion is a store-house of experiments, which will be of great use to the lecturer on physiology. Scarcely enough stress, in view of existing impressions with regard to it, is laid upon the utter inapplicability of all the ordinary modifications of Pettenkofer's test for the determination of bile-acids in the urine. That of Strassburg, which is given, and which consists in adding a little cane sugar to urine containing bile-acids, dipping a piece of filtering-paper into it, letting it dry completely, and then adding a drop of pure sulphuric acid, we have found no more satisfactory than the rest. If the bile-acids are present, according to Strassburg in a quarter of a minute a beautiful violet color appears, which is best seen by holding the paper up to the light and looking through it. Dr. Brunton states, however, that in all doubtful cases, and wherever accurate results are required, the bile-acids should be separated before applying the test. We believe no other method than this, as directed by Hoppe-Seyler, is available for accurate investigations, and this is so long and tedious as to be quite beyond the use of the practitioner.

Among the secretions are considered milk and urine. This part of the work is less complete than the others, and is more of the nature of a compilation from the physiological chemistries of Gorup-Besanez, Kühne, Hoppe-Seyler, and others. It is nevertheless very useful, and adds greatly to the completeness and utility of the entire treatise.

To the book is added an admirable appendix of "Practical Notes on Manipulation," including manipulation of glass tubing, solution and ebullition, evaporation, filtration, etc.

MINERAL SPRINGS OF NORTH AMERICA: HOW TO REACH AND HOW TO USE THEM. By J. J. MOORMAN, M.D., Physician to the White Sulphur Springs, etc., etc. Crown 8vo, pp. 295. Philadelphia, J. B. Lippincott & Co., 1873.

The first edition of this work was issued, in pamphlet form, in 1839, as a directory for those seeking the benefits of the White Sulphur Springs in Virginia. Since that time, in successive editions, it has undergone a great increase in scope, until this, the seventh, embraces all the well-known springs of the Northern Continent of America.

Dr. Moorman has given, as might have been expected, a much larger space to the springs of Virginia than to those of any other State. This is partly owing to the fact of the much greater development of their natural advantages in that part of the country than elsewhere, but mainly, doubtless, to his own familiarity with them. His directions are sound, clear, and practical, and will be of use to many physicians in influencing their advice to patients. The analyses given of the various mineral waters are derived from the best authorities.

The mechanical execution of this book leaves nothing to be desired, while its size will make it very convenient for reference.

THE MINERAL SPRINGS OF THE UNITED STATES AND CANADA; with Analyses and Notes of the Prominent Spas of Europe, and a List of Seaside Resorts. By GEORGE E. WALTON, M.D., Lecturer on Materia Medica in the Miami Medical College, Cincinnati, etc., etc. Small 8vo, pp. 390. New York, D. Appleton & Co., 1873.

This is a very good book, especially in its arrangement; the various springs being classified, not according to regions, but according to their physical peculiarities and medicinal effects. A slight tendency to the absurdity called "popular medicine" only excepted, the scientific portion of the work is well done. Clear directions as to the railroad routes, illustrated by maps, add greatly to its value both to patient and of physician.

GLEANINGS FROM OUR EXCHANGES.

KRAUSPE ON EXTENSIVE DILATATION OF THE ARTERIAL SYSTEM.—Dr. Krauspe records (*Berliner Klinische Wochenschrift*, March 17, 1873) a case from the polyclinic of Dr. Nothnagel of Freiburg, in which a condition of aneurismal dilatation of the vessels was found extensively distributed over the arterial system. A man, aged sixty-four, short and thin, and suffering from an acute exacerbation of chronic bronchitis, which had probably existed for many years, was found to present the following condition after the acute attack had passed off. There were symptoms and physical signs of chronic bronchitis and emphysema. Enlargement of the right ventricle was not demonstrable locally; the left ventricle was hypertrophied and dilated. The cervical veins were excessively dilated, with regurgitation, but no pulsation. The kidneys were congested. There was no subcutaneous œdema. In various parts of the arterial system there was evidently present aneurismal dilatation of the vessels, both as smaller circumscribed aneurisms, and as extreme dilatation of considerable portions of the arteries. The vessels of the neck presented this condition to a very striking degree and extent. The right common carotid artery, apparently normal below, speedily became extremely dilated, reaching the diameter of 2.5 centimetres; and there was corresponding dilatation of the right external and internal carotids. The left common carotid artery and its two branches were equally dilated with the vessels of the right side, but the main trunk was at the same time considerably elongated. The thyroid and lingual arteries of both sides were visible, dilated, and tortuous. The temporals were narrower than usual. All the dilated arteries in the neck were pulsating strongly. The radial arteries were somewhat tortuous; the walls were not rigid, their circumference was moderate, the tension rather small, and the pulse-wave low. The right brachial artery was somewhat tortuous, and in its diameter and strength of pulsation almost equalled the axillary. The left brachial was decidedly smaller than the right, and markedly different from the corresponding axillary, which was dilated nearly to an aneurism. The abdominal aorta could be very easily felt, and was much elongated and tortuous; it was not perceptibly dilated. In the right femoral artery was found a distinct but not great dilatation, with weak systolic murmur, and the walls of the vessel in its whole course were somewhat rigid. On the left side a similar aneurismal dilatation was doubtfully present. In the popliteals and tibials, nothing abnormal was discovered. In short, there was dilatation and elongation of the carotid arteries and some of their branches, and of the brachials (not marked); small sacculated aneurisms of the femoral and left axillary arteries; and elongation only, so far as could be discovered, of the abdominal aorta. There was probably also dilatation of the ascending aorta; for, with hypertrophy of the heart, there was no marked dilatation in the subclavian or brachial arteries.

Such enormous widening of the vessels, says Krauspe, must clearly cause great obstruction to the blood-stream; and this is compensated for by the hypertrophy of the left ventricle. In regard to the relation of hy-

pertrophy of the left ventricle to thickening of the arterial walls, one might ask which of the two changes in the present case had been the first, the vascular or the cardiac. The author believes that the aneurismal change in the vessels was the original disease, because in the first place there were sacculated aneurisms in addition to the general dilatation; and, secondly, because there was not dilatation of all vessels under the same conditions. There was probably then an aneurismal diathesis to start with, and a consequent hypertrophy of the heart.

The cervical veins have been already described as excessively dilated in this patient. The external jugular veins were like thick cords. The right internal jugular vein was uniformly dilated, reaching, at the point corresponding to the valves, the breadth of three centimetres. Krauspe confesses that this dilatation of the veins of the neck is very difficult to account for. It was probably due, he thinks, to the long-standing emphysema, with some aggravating local cause, such as the pressure of the dilated aorta, or the effects of a large abscess of the neck, from which the patient had suffered many years before.

In February, 1873, a woman, aged 23, came to him with severe pain about the middle and just outside of the right tibia, of two or three years' standing; much more severe during past year. Attacks were like flushes, extending generally upward, lasting from a few minutes to one or two hours. No cause named, unless fatigue. There was slight discoloration of the skin, as large as a pin's head. Blood-vessels of skin not enlarged. On pressure, a body of the size of a bean was felt, rolling under the fingers, seemingly in the cellular tissue, and attached by a small point to the skin; not tender, except when pain was severe. Tumor was removed, with the attached piece of skin. No pain since. Tumor was as large as a bean, firm, imbedded in cellular tissue; connected with capsule, but otherwise free. Being cut open, a white surface was presented, of cartilaginous hardness, without blood-vessels. No nerve-cells were found with a moderate magnifying power.

The first and best general description is given by Wm. Wood, in *Edinburgh Medical and Surgical Journal*, in 1812; it also received its name from him. Dr. J. C. Warren, the elder (Surgical Observations on Tumors, p. 59), describes three cases; in two, removal was not allowed. In the third, a man had suffered seven years, and for four very severely, from pain about three inches below the knee. When seen by Dr. Warren, there was an open ulcer, following the use of caustics; physical condition bad, with cough, purulent expectoration, quick pulse, emaciation, etc. Amputation was performed, and patient recovered in three months.

These tumors occur in adults; and in women rather than men, in the proportion of four to one. Paget (Surgical Pathology, Second American edition, p. 393) says, "They may be formed either of fibro-cellular or fibrous tissue, in either a rudimental or a perfect state," or "they may be fibro-cartilage."

Wedl (Pathological Histology, p. 401) found "a new formation of connective tissue which, at any rate for the most part, retained an embryonic character. Not a trace of nerve-substance could be discovered in the interior of the nodule." Billroth found muscle-cells, but no nerves; Bärensprung, peculiar knots upon the blood-vessels around tumor. Paget thinks they are not neuromata, because nerve-fibres cannot be demonstrated in them; because neuromata are often multiple, are unlimited in size, and are most frequent in the male sex; these occur singly, are smaller in size, and more frequent in women.

Some observers consider these tumors to be developments of the Pacinian bodies.

Virchow (Die Krankhaften Geschürelste, vol. iii. p. 241) says that he has seen one removed from the knuckle, which a nerve entered and left, and the mass was made up of obscure nerve-fibres. He adds, that most pathologists of the present day would call such tissue briefly fibroid, fibro-plastic, or fibro-nuclear, and thinks that we need more and more exact observations.

There is a point worth noticing. Cartilage is not known to have nerves; it is not sensitive; when inflamed, it is extremely sensitive, but even then it has no nerves, so far as is known. Has not cartilage assumed new functions? In painful subcutaneous tumors, has not connective tissue similarly assumed new functions?

Case of Renal Abscess, with Contained Calculus, successfully Relieved by Operation.—This rare case is reported by Mr. Thomas Annandale, in the *Edinburgh Medical Journal*. The patient, a farmer, aged sixty-three, had been suffering for several weeks from gastric and renal derangement, the symptoms increasing in severity, and finally pointing pretty clearly to some affection of the right kidney. The first examination determined that there was tenderness on pressure over the lower half of the right kidney, and below it in the direction of the ureter. A very slight fulness in the same region was noted, but no marked swelling could be detected. No fluctuation could be felt, and the introduction of a fine trocar in the lumbar region gave no result.

At the expiration of nearly a month, he was seen for a second time by Mr. Annandale, and upon this occasion his symptoms were very much worse. It was now thought that deep fluctuation could be detected through the anterior abdominal wall, just below the region of the affected kidney, and, in accordance with the urgent request of the patient, it was decided to try and do something for his relief, and make at least an exploratory incision. The incision was made through the abdominal wall, in the situation and direction of the incision employed for the ligature of the common iliac artery. Pushing aside the peritoneum and abdominal contents, the psoas muscle was reached with the finger; by the inner side of this muscle an abscess was detected, and within this abscess-cavity was found a calculus, the size of a horse-bean, which was seized with the forceps and removed.

The operation gave great relief, and the patient improved steadily up to the fifth day, when a small quantity of thin, feculent matter passed the wound, and fæcal matter continued to pass the wound for nine days after the operation, from which time no further discharge was observed. By the end of a month the patient had apparently made a good recovery.

In commenting upon this case, Mr. Annandale remarks that the whole trouble had its origin in a renal calculus, which had given rise to suppuration and ulceration, and in this way escaped from the kidney. The abscess, passing downwards, was preparing to empty itself into the ascending colon or cæcum; in fact, a small opening of communication with the intestine had already been made, and the further destruction of the intestinal wall was only prevented by the free escape of pus. The result of this case affords additional encouragement to surgeons to operate early in cases of abdominal or pelvic abscess, in which the timely use of the knife may relieve suffering and even save life.

Acaro-dermatitis Autumnalis.—Dr. J. W. Southworth, of Toledo, Ohio, describes, in the *Detroit Review of Medicine and Pharmacy*, this affection, which is found mostly on the lower extremities of laborers and others who frequent vineyards and harvest fields of grass or grain, in the latter part of the summer and autumn. It

presents itself as a more or less pruritic and intense erythemation, in patches of greater or less size, according to the number of parasites present. Occasionally, wheals are formed in the immediate vicinity of the animalcules, especially in sensitive subjects who have indulged in much scratching. The skin may be lacerated and swollen. Violent inflammation of the latter, and of its underlying tissues, resulting in sloughing, suppuration, or gangrene, to such an extent as to imperil life or necessitate amputation of the affected limb, has been known to occur. This latter is reported to have happened among some troops at Martinique.

Its cause is the attacks of the acarus autumnalis, or harvest-mite, which, on account of its bright-red color, is also called *rouget*, or *bête rouge*, by the French. Septus autumnalis is another synonym. Neumann states that Gruby has described this parasite in the *Allg. Med. Zeitung*, 1863, under the head of aracnide.

The diagnosis is quite easy, as the acarus is readily found, with its blood-distended abdomen, partially imbedded in the inflamed tissues; a minute, red, oval body, requiring a little care and close inspection to detect in some instances. It may be found on almost any portion of the skin, but is chiefly met with on the inferior extremities.

The treatment is by careful removal of the parasite with forceps where there are only a few; and when the reverse is the case, the application of some efficient parasiticide, as a spirituous solution of carbolic acid, corrosive sublimate, or camphor sufficiently diluted with water to prevent any increase of the existing inflammation.

The after-treatment may be of any of the usual cooling, bland, or astringent lotions, such as solution of acet. plumbi or acet. ammoniæ in water, vinegar and spirits of wine, camphor-water, etc., all of which must be applied according to the principles of surgery adapted to traumatic dermatitis.

[We think this is the same insect which is known in the Eastern and Middle States as the *tick*, and which is met with abundantly in the dry, sandy regions where one species of whortleberry grows.—Ed. *P. M. T.*]

Sympathetic Disease in the Marrow of Bone in cases of Internal Disease (Dr. E. Ponfick: *Virchow's Archiv*, vol. 56, 4th part, 1872).—Before Neumann and Bizzozero had pointed out the close relationship between the parenchyma of the spleen and medulla of bones, and had likewise pointed out the important part this medulla of the bones plays in the formation of the blood, Von Recklinghausen demonstrated, by means of experiments, the analogy existing between certain elements of both organs. He found that after the introduction of insoluble coloring-matter into the circulation, a rapid passage of the same took place into the parenchyma of the most various organs, among them the medulla of bones. He also showed most conclusively how great a part the contractility of certain medullary elements plays in the vital processes of the internal organism.

The experiments which Ponfick has made at the suggestion of Von Recklinghausen, to carry out still further these views, have led to the following results:

These cell-forms belonging to the medulla of bones, which resemble morphologically the elements of the "spleen-pulp," correspond also, in general, with the latter in their reaction with the granules of the coloring-matter conducted to them through the blood; and also in all important and essential points. The two first-named observers demonstrated that analogous features in the circulation existed both in the spleen and medullary structure of bone, since the small arteries pass directly into disproportionately larger blood-vessels, bounded by an extremely thin and delicate membrane, the analogue of the cavernous veins of the spleen. In the experiments performed by Ponfick upon animals deprived of their spleens, this fact has been established, viz.: That the cinnabar introduced into the blood of animals previously deprived of their spleens arranges itself in the same places and in the same way in the marrow of such animals, thus proving the entire independence of the medullary and splenic deposition of the cinnabar, as well as the co-ordinate position of the two structures in relation to the blood.

Change of Color in the Hair (*Lancet*, May 7).—Several historical and well-known cases (as those of Maria Theresa, Ludovico Sforza, and Mary Stuart) corroborate the simple but affecting statement made by the Abbé Lefevre the other day in the Tichborne trial in reference to the sudden change of color his hair had undergone. He had heard, he said, of the death of his father, and on the following night dreamt that the details of his death were enacted before his eyes. He awoke terribly agitated, and found that his hair had become white. A curious instance lately came under our observation, in which a black retriever puppy received a violent kick from a horse, which caused fracture of the thigh. By the time the fracture had united, the dog's hair had changed from a deep black to a light brindle. The dog is now fully grown, but the hair has not recovered its original color.

To what can this change be attributed? The answer is not easy. Is it due to the extrication of air? Is it a consequence of the absorption of pigment, or the result of the action of some chemical compound, as an acid, eliminated by the skin? Under any circumstances it is singular that the influence should be limited to the hairs alone, and should not, apparently, otherwise affect the integument. The circumstances under which it usually occurs point to the nervous system as a principal agent, and this is supported by the occurrence of white hairs in the eyebrows and temples after severe attacks of neuralgia. Still, it may be asked, is it an instance of the direct action of the nervous system upon the hair-cells, or indirect upon the vessels of the surface? It would be interesting to know how the white color makes its appearance—from the apex to the root, or *vice versâ*.

The Pathology and Treatment of Hooping-cough (*Ib.*).—In a paper published in the *Swiss Correspondenzblatt* of April, 1873, Dr. Rudolf Meyer, of Zurich, gives an interesting account of some auto-laryngoscopic observations he made whilst suffering from a well-marked attack of this disease. He found the mucous membrane of the under-surface of the epiglottis and of the adjoining parts of the entrance into the glottis, and especially that covering the so-called arytænoid cushion, swollen and red, whilst that of the adjoining parts of the pharynx was also distinctly inflamed. The vocal cords and the lateral and internal parts of the larynx were normal. The inflamed parts were highly sensitive, the least touch bringing on spasmodic cough. In another case, occurring in a middle-aged woman, the same conditions were ascertained to be present. Dr. Meyer effected a cure in his own person in a few days by insufflating some powdered alum; but on trying the same plan with the lady, retching was induced, and he was obliged to use solutions of alum and tannin, which proved successful, though less rapid in action. The plan suggested by Dr. Meyer may be carried out with advantage in adults who are steady, but it is difficult to see how it could be applied in children.

Causes producing the Development of the Sexes (E. Baust: *Stuttgart. Journal für Kinderkrankheiten*, 1872, Hefte 3-4).—The first point considered in this work is the natural tendencies in the development of the sex of the embryo. Under this head there are three

hypotheses. 1. All embryos tend to become females,—a very old theory. 2. The embryo from its beginning has its peculiar sex (Carus, Rathke, Burdach). 3. The theory of St.-Hilaire, Ackermann, Müller, and others, that the embryo possesses no sex, but gradually develops into a male or female according to its inherent tendencies. A variety of experiments upon plants gave the interesting results that by means of heat, light, and absence of moisture we may produce specimens of the male plant, while in the shade, dampness, and by means of manure we can produce more female plants. Hence we may assume the following law: Influences which predispose the seed to rapid development will be apt to engender females, while influences of an opposite nature will most likely produce males.

In accordance with this theory is the fact that honey-bees, the workers, which grow to maturity under meagre nourishment, may become perfect females if while in a larval condition they are fed with the food of the queen bee.

There is also another important element in the development of the sexes, drawn from the difference in the ages of the parents. The investigations of Hofacker, Sadler, Göhlert, and Boulenger have shown that when the age of the husband greatly exceeds that of the wife, more male children are born, and when the father is younger than the mother, more girls than boys are born.

Fraenkel on Placental Syphilis.—Dr. Ernest Fränkel (*Archiv für Gynaekologie*, April, 1873), in a most interesting and exhaustive paper on this subject, illustrated by some well-executed plates, and recording in detail the particulars of more than twenty cases, arrives at the following conclusions:

1. The placenta may become syphilitic, and there are certain characteristic indications of this.

2. The syphilitic placenta occurs only in hereditary or congenital syphilis in the fœtus.

3. The seat of the disease is different, according as the mother remains healthy and the syphilitic virus is communicated directly from the father to the ovum by means of the spermatozoa, or according as the mother is diseased.

In the former case, the affected fœtal villi of the placenta degenerate through cellular granulation, with consecutive obliteration and atrophy of the vessels, complicated frequently by marked proliferation and condensation of the epithelial covering of the villi.

4. In the second case, when the mother is syphilitic, the three following conditions are possible:

a. The mother, through the act of impregnation, is simultaneously affected with syphilis with the fœtus; diffused syphilis of the placental villi may then develop itself, but primary infection of the maternal parts—endometritis placentaris—is not excluded.

b. The mother has been infected with syphilis before or shortly after conception. The placenta may remain normal, or become diseased under the form of endometritis placentaris gummosa, or (according to Virchow) in a narrower sense—endometritis decidualis.

c. The mother becomes infected only during the latter months of pregnancy (seventh to tenth month). It then generally happens that, in case the father was healthy at the time of impregnation, the fœtus as well as the placenta are exempt from the alterations described above.

5. The infection of the fœtus by passing through the genital canal of the mother is rare, and not yet proved beyond doubt.

The Blood in Relapsing Fever.—According to the observations of Obermeier (*Medical Times and Gazette*, March 29, 1873), the blood of persons laboring under relapsing fever contains peculiar filiform bodies, which exhibit very active spontaneous movements. A drop of blood extracted from such a patient, and mounted, as usual, with the necessary precautions, presents these bodies among the corpuscles when magnifying powers of 400 to 900 are employed. They appear as extremely delicate threads of the thickness of a fibrous filament, and of the great length of one and a half to six times the diameter of a red blood-corpuscle or more. Several of the bodies may be seen on the field at once; and so long as the preparation is fresh, they exhibit active movements,—not only changes of form, moving and alternately coiling and uncoiling, but also changes of locality, by which they slowly or suddenly escape from the field of view. Altogether, the movements remind one of spermatozoa. Hitherto, Obermeier has found these filaments during the fever only, and shortly before or during the crisis,—not in the interval. Sometimes they are to be seen one day, and not the next. He could not find similar bodies in the blood of healthy persons, or of persons suffering from other diseases. Of their nature, he will not yet give a decided opinion.

The Phrenic Nerve passing through a very Narrow Island (Insel) of the Subclavian Vein (Wenzel-Gruber: *Virchow's Archiv*, January 10, 1873).—This peculiarity was observed in March, 1872, on the left side of a male subject which had been given to the medical students for the purpose of making a preparation of the vessels and nerves of the trunk.

The left subclavian vein divided into two branches in front of the anterior scalenus muscle, 1.4 centimetres exterior to its junction with the internal jugular vein, forming the left anonymous vein. There was an anterior as well as a posterior branch. The anterior branch was 7.8 millimetres, the posterior one was 6 millimetres wide. After running a distance of 4 millimetres, the branches united to form a common trunk. Thus the left subclavian vein, 1 centimetre external to its junction with the internal jugular vein, had formed a very narrow island (*insel*). This had the appearance of a very narrow opening, which possessed a transverse diameter of 4 millimetres and a vertical diameter of 2 millimetres. The phrenic nerve passed obliquely through this ring from above and without downwards and inwards. The nerve passed over the posterior branch, while the anterior branch lay upon the nerve.

Thus the left subclavian vein looked as though it were perforated by the left phrenic nerve.

A similar case has never been, so far as the author knows, reported in the literature of anatomy. The preparation is in his cabinet.

Alterations of the Nervous System of the Great Sympathetic in Cases of Constitutional Syphilis.—Dr. Petrow (*Virchow's Archiv*, Band 57, Heft 1, 1873), on examining portions of the plexus of the great sympathetic which he had taken (ten to twenty-four hours after death) from the bodies of individuals affected with acquired constitutional syphilis, has stated two sorts of pathological changes: 1. Modifications of the protoplasma of nervous cells, which become loaded with brilliant pigmentary corpuscles, increasing with the age of the disease, and often accompanied by colloid transformation of the cells; the cells of the endothelium surrounding the nervous cells frequently undergo the same gelatiniform transformation, and cannot then be distinguished from the nervous cells. These changes can exist without the interstitial connective tissue being impaired. 2. Modifications of the interstitial connective tissue with hyperplasia of the fibres, constituting large, irregular fasciculi, which push aside and compress the nervous cells and fibres. The cells are then atrophied, irregular, and dotted with pigment, whilst the fibres are flattened, and their myelin shows slight granulations.

THE TEMPERATURE IN DIPHTHERIA (by Dr. G. Faralli: *Le Mouvement Médical*, April 26, 1873; from *L'Imparziale*, March 1, 1873).—The author studied an epidemic of diphtheria with a view of noting the state of the temperature,—a subject which has given rise to much discussion. His observations are as follows:

1. At the onset, chills, vomiting, convulsions, delirium, and in a few hours the thermometer rises to 40° (C.). From this moment the temperature gradually falls until the third or fourth day, when the patient becomes apyretic (benignant form).

2. In other cases the temperature rises again on the fourth day, but never to the degree reached at the onset of the disease. This is due to the formation of new diphtheritic patches on the side previously unaffected, or to the engorgement of glands.

3. This secondary infection is particularly evident in the typhoid form, the column of mercury continuing to ascend until the moment of the patient's death.

These characters are subject to variations from complications; as for example in cases where stenosis of the larynx causes death, the temperature may remain normal.

PATHOGENIC INFLUENCE ON THE SKIN OF BROMIDE OF POTASSIUM EMPLOYED INTERNALLY.—In the *Wiener Med. Wochenschrift* (No. 6, 1873), Dr. J. Neumann has investigated the above subject. The author recalls the observations of Voisin of Paris, and Mitchell of Philadelphia, according to whom the employment of bromide of potassium in weak doses brings on eruptions similar to acne, with itching and the consecutive formation of indurated tubercles; whilst the prolonged use of the substance gives rise to the production of red tumors, which often become sore, of carbuncles, anthrax, eczema, and nettle-rash. Dr. Neumann states that, for his own part, he has observed eruptions very much like molluscoid acne coming on in successive outbreaks, and, in another case, a carbuncular eruption consisting of infiltrated tumors, with considerable loss of substance in the centre. The author inclines to think that the bromine passes into the blood, and thence into the various glands of the skin, and he accounts thus for the production of the eruption. It is known that the presence of bromide of potassium has been observed in urine, saliva, and the secretions of the skin.

ULCERATION OF THE TRACHEA AFTER TRACHEOTOMY (*British Medical Journal*, May 3).—Mr. Bennett May exhibited the trachea of a child, showing an erosive ulcer in its interior, which had terminated fatally by hemorrhage after tracheotomy. The operation had been done for œdema of the glottis following the imbibition of boiling water. The trachea-tube was removed on the fifth day, and, on reintroducing it a few hours afterwards to relieve the dyspnœa caused by the accumulation of mucus at the wound, a sudden gush of blood deluged the parts and destroyed the child. The ulcer due to the pressure of the tube was not above a line in depth, and appeared to have opened one of the anterior thyroid veins.

CARBOLIC ACID IN DIPHTHERITIS (*Deutsche Klinik*, No. 20, 1871; quoted from *Journal für Kinderkrankheiten*, vols. iii. and iv., 1872).—Dr. Helfer, in Leipsic, has tried this drug in a series of cases of scarlet fever complicated by diphtheritis, after all other remedies had failed. It was used as a gargle in the strength of 1 to 200 every half-hour; for the "atomizer," 1 to 50 every two or three hours.

INVERSION OF THE UTERUS (*British Medical Journal*, May 3).—Mr. Prankerd read to the West Somerset Branch of the British Medical Association notes of an interesting case of inversion of the uterus which occurred a week after parturition, and, having resisted ordinary modes of reduction, gradually gave way under the continued employment of an air-pessary.

MISCELLANY.

AN ADVENTUROUS LIFE.—*The British Medical Journal* of April 26 contains the following account of the career of the late William Brydon, C.B., Surgeon-Major Bengal Army, and Highland Rifle Militia:

"He received the appointment of Assistant-Surgeon in the Honorable East India Company's Service, and landed in Calcutta in October, 1835, and, after a short stay there, was ordered up-country with European recruits. At Kurnaul he was temporarily attached to the artillery and Her Majesty's 13th Regiment, till posted to the 4th Lancers (native) as Assistant-Surgeon.

"He went twice with Sir Henry Fane, and a third time with the Governor-General, Lord Auckland, on escort-duty to Runjeet Sing's court, then in all its glory at Lahore.

"In 1839, he was put in charge of the 5th Native Infantry at Ferozepore, and marched with them through the Punjaub and Kyber pass, in the ill-fated expedition to Afghanistan. Here he saw much service when attached to Shah Soojah's 6th Regiment, and at the destruction of the robbers' forts in the Toormat Valley. Returning to Cabool before the disturbances broke out consequent on the vacillation of the British leaders, he was in the Balahissar for about three weeks; he then removed to the cantonments, and was in the fatal retreat in January, 1842. He suffered unparalleled privations in the march through the tremendous passes and narrow gorges of the Koora Cabool from the fire of the enemy and the inclemency of the weather, reaching Jellalabad wounded in the knee, badly in the left hand cut across by a sabre, and seriously in the head by an Afghan knife, which, but for a *Blackwood's Magazine* in his forage-cap, must certainly have killed him. He was thus the first and "last man" (the *sobriquet* by which he was known among Europeans in India), and gave the doleful tidings of the fate of the army (including camp-followers) of 16,500 that had miserably perished. He was one of the 'illustrious garrison' that held Jellalabad under General Sale, and, on Sir George Pollock reaching the beleaguered fortress, was attached to the 33d Native Infantry, and with that general retraced his steps to Cabool with the army of retribution, which on its return to Ferozepore in 1843 was received with high honor by the Governor-General, Lord Ellenborough. From this time he was chiefly in the Bhopal State—the Begum of which was honorably distinguished for her loyalty to Britain in 1857—till promoted in 1849 to the rank of Surgeon and posted to the 40th Native Infantry, with which he was sent to Burmah in 1852, being present at the taking of Rangoon, Prome, etc.

"After eighteen years of active service, he returned to his native land for three years on sick-leave, at the expiry of which India again, in the throes and convulsion of a rebellion, received his valuable services. During the siege of Lucknow he was severely wounded in the lower part of the spine by a rifle-bullet, which passed through his body from the left to the right side, and

from which he suffered during the rest of his life. In 1857, he was sent in charge of the field hospital from Lord Clyde's army at Cawnpore to Allahabad, holding various charges there, and subsequently being surgeon superintending at Dinapore. In 1859, he retired from the service on his well-earned laurels. Few medical officers have seen and passed through such arduous service, and none could grudge the honors conferred by his country in decorating him with medals for Jellalabad, Cabool, Burmah, clasp for Pegu, clasp for Lucknow, and Companion of the Bath in 1858.

"Settling down in the quiet Highland retreat of Westfield, Ross-shire, he sought rest in country pursuits, yet was ever ready to administer relief to the many who sought his advice. He was carried to his last resting-place in the Rosemarkie Burying Ground, followed by sorrowing relatives and the heartfelt regret of friends and neighbors, for a better and braver man than William Brydon one rarely met."

An Ethnological War.—The *Lancet* says that the enmity between France and Germany has been transferred from the battle-field to the lecture-room, and M. Quatrefages has been eagerly followed in his disparaging speculations as to the genesis of the North German race. M. Quatrefages, on the publication of his views last year, was held to have done more harm to his own reputation than to the Prussians, and scarcely deserved the elaborate and conclusive refutation he experienced at the hands of Professor Virchow. If M. Quatrefages could prove that the Prussians came originally from the table-lands of Central Asia, he would only be doing what Dr. Prichard long ago did for the whole Celtic race,—the French part of it included. But, arguments from anatomical structure and moral development apart, the question of language is enough to dispose forever of all attempts to find a Mongol progeniture for the North Germans,—a question in which the French *savants* are as little a match for their German antagonists as Benedetti was for Bismarck, or MacMahon for Moltke.

Diseased Meat.—The *British Medical Journal* of May 10 says that, "At the police court in Dublin last week, a woman named Murtag was fined by the presiding magistrate the sum of £10 for exposing meat which was diseased for sale. The offender would have been sentenced to imprisonment but for the mistaken clemency of the solicitor for the Public Health Committee, who were the prosecutors, who begged the magistrate to inflict a fine because the defendant was a woman. Among the many privileges claimed for the sex, this is one of the strangest and least admissible. Women may be allowed to lecture us, to govern us, or to doctor us, but not to poison us."

Cholera in Austro-Hungary.—From the same source we learn that "The reports from Silesia on April 17 show that cholera had entirely ceased in that province of the Austrian empire. From its outbreak on November 28, 1872, to the above-named day, 702 cases had occurred in thirty localities with a population of 35,110 inhabitants; 374 had died, and 328 recovered. In Hungary, cholera has reappeared in several districts. In Pesth, which had been free since January 20, it broke out again on March 26. From March 26 to April 15 there were 74 new cases, of which 15 recovered and 39 died. In Galicia, during the first half of April, 201 new cases occurred; making, with 42 remaining under treatment, 243, of which 89 recovered and 88 died.

Physiological Observations on the Action of Light.—At a recent meeting of the Edinburgh Royal Society, Professor Dewar read a paper on further physiological experiments on the action of light, made by Dr. McKendrick and himself. He detailed the effects of light when the various parts of the eye were used for the purpose of determining electro-motive values, and also the effects of varied alkaloids on the sensibility of the retina. He showed that the moment light impinged on the retina the electro-motive force rose, and that there was also an increase of electro-motive force the moment light was withdrawn. They also traced the action of light not only into the optic nerve, but into the brain. The paper concluded with the measurement of the effects of different luminous intensities on the eye; and the authors showed that the experimental results agreed very closely with Fechner's psycho-physical law.

Lord Shaftesbury, the great social reformer, told, in a recent speech, of his having whitewashed and painted one of the dark houses occupied by a family in one of the foul districts of London, and a short time after returning to find it worse than ever. He said, "What on earth is this?" And the reply was, "Please your honor, the house looked so cold and uncomfortable that I sent for a sweep and asked him to give us a few warm touches."

Liberal.—A recent daily paper says, "As an encouragement to medical men, who certainly have enough to discourage them, we must mention the liberality of a grateful father in Augusta, Maine. Dr. C—— was called to attend a little child, and, after assiduous attention for three or four days, succeeded in rescuing the sufferer from the scarlet fever. The grateful father sent to Dr. C—— a fee of $1000."

In the report of the Health Department of New York for the year 1872, alcoholism is returned as the direct cause of death in 314 cases; delirium tremens in 102 cases; and, indirectly, intemperance is given as the cause of death in altogether no less than 826 cases.

Medical Society of the State of Pennsylvania.—The annual meeting of this body will be held in Carlisle, beginning on Wednesday, June 11.

Dr. David Skae, for twenty-seven years physician to the Morningside Asylum (for the insane) at Edinburgh, died recently, in his sixty-fifth year.

A second human skeleton (pre-historic) is now said to have been discovered in the caves of Mentone. Human remains have also been found near Laval.

The cave in which they were found contained chipped flints, incised bones, and a hearth with calcined bones, together with the remains of many animals, among which the cave hyena, the common fox, the woolly rhinoceros, the horse, and the reindeer are enumerated. In a quarry in the neighborhood of the cave an interesting series of animal remains has been found, including the cave hyena, the cave lion, the marmot, a large hare, the mammoth, and the woolly rhinoceros, besides the fox, boar, horse, and several oxen and deer. Numerous bones of birds were also found.

THE Paris correspondent of the *Lancet* says that each of the four large hospitals of Paris where clinical medicine is officially taught has recently been endowed with a special and complete laboratory for researches in morbid anatomy, histology, and medical chemistry. Morbid specimens will thus be examined in every way by the gentlemen attached to the laboratory, who are appointed by the Minister on a list of presentation drawn up by the professors at each hospital. Those now in office are Dr. Lionville, at the Hôtel-Dieu; Dr. Nepveu, at La Pitié; Dr. Cornil, at La Charité; and Dr. Hybord, at the Hôpital des Cliniques.

THE MEDICAL SCHOOL AT NETLEY.—The session at Netley was opened on April 2, by an introductory lecture from Dr. De Chaumont, Assistant Professor of Hygiene. The numbers attending the course are as follows: Candidates for Indian army, sixteen; for navy, fourteen; naval surgeons on half-pay, six; army surgeons-major, five; army surgeons, twelve. The arrivals of invalids from India and other foreign stations have been very numerous lately, and nearly a thousand cases are now under treatment in hospital. Dr. Balfour, C.B., has assumed the duties of Principal Medical Officer.

ABORTION-MONGERS.—The *Clinic* says, "Such is the impunity with which this practice is carried on in Stamboul, that a pharmacien absolutely has for his sign the representation of a fœtus complete. A practitioner accused of this crime advanced in his defence the fact that he himself had invented an instrument for procuring abortion easily and satisfactorily."

AT the one hundred and seventh annual meeting of the New Jersey Medical Society, just closed at Mount Holly, Dr. T. J. Thompson was elected President; Drs. Schenck and Ryerson, Vice-Presidents; Dr. Pierson, Secretary. The meeting was well attended.

A NEW ARTICLE OF DIET.—Foreign advices state that the marmot, an animal analogous to our "woodchuck" or "ground-hog," has been introduced into the Parisian market, and has met with much favor among epicures.

MODERN INDUSTRY.—A Vienna journal contains the following announcement: "Anna Agrikol, sick-nurse, watches dead bodies, repairs straw chairs, applies leeches, and makes pastry desserts, and delicacies."

WEEKLY RETURN OF DEATHS AND INTERMENTS IN PHILADELPHIA FOR THE WEEK ENDING SATURDAY, MAY 31, 1873.

The surface of the cistern of Barometer is located 71.92 feet above the mean level of the sea.

Barometer corrected for temperature, elevation above sea, and instrumental error.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 27, 1873, TO JUNE 2, 1873, INCLUSIVE.

HARTSUFF, ALBERT, ASSISTANT-SURGEON.—Relieved from duty in Department of the Lakes, and ordered to Department of the Platte for assignment to duty. S. O. 105, A. G. O., May 26, 1873.

MIDDLETON, J. V. D., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Buford, D. T. S. O. 107, Department of Dakota, May 22, 1873.

YEOMANS, A. A., ASSISTANT-SURGEON.—Relieved from duty in Department of the East, and ordered to Department of the Missouri for assignment to duty. S. O. 105, c. s., A. G. O.

STYER, CHARLES, ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Chattanooga, Tenn. S. O. 102, Department of the South, May 27, 1873.

SATURDAY, JUNE 14, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF HYDROTHORAX IN WHICH PARACENTESIS WAS PERFORMED.

Delivered at the Philadelphia Hospital, May 31, 1873,

BY WILLIAM PEPPER, M.D.

(Continued from page 563.)

GENTLEMEN:—As I before said to you, the only plausible explanation of the fact that the pleural effusion in this case of suspected cirrhosis of the liver is limited to the right side is to be found in the peculiar condition of the lungs and heart. A very careful examination of these was made on May 20, with the following results:

The *right* thorax was markedly distended, with slightly bulging intercostal spaces. The respiratory movements of this side were almost entirely abolished. There was absolute flatness upon percussion, extending from the lower line of liver dulness up to the second rib, above which there was sub-tympanitic resonance. Respiratory murmur was almost entirely absent over this area of dulness, nothing being heard but feeble and distant bronchial breathing. Over the clear area at the apex there was rude broncho-vesicular breathing. Vocal resonance and fremitus were almost annulled. On placing the fingers of the left hand in the fourth, fifth, sixth, and seventh costal interspaces of the right side, and percussing sharply over the uppermost finger, a feeble but distinct sense of fluctuation was perceived by the lower fingers. This was best observed when the patient was sitting.

The respiratory movements of the *left* thorax were exaggerated; there was no bulging of the intercostal spaces, but, on the other hand, during each inspiration there was a marked retraction of the soft tissues in the lower interspaces, and of the epigastrium. Percussion-resonance was everywhere normal. The respiratory murmur was clear throughout, with some coarse, moist crackling at the lower part of the posterior surface.

The position of the apex-beat of the heart varied with the respiratory movements. In the recumbent posture, it descended during full inspiration to the sixth interspace, about three-fourths of an inch to the left of the left nipple; while during expiration it rose to the fifth, and finally to the fourth interspace, just within the line of the left nipple.

With each systole of the ventricles there was distinct retraction of the nipple and soft tissues immediately surrounding it; this was most marked during expiration, evidently because the nipple shared in the general retraction of the lower intercostal spaces which took place with inspiration. The retraction of the nipple was, however, quite distinct from this latter respiratory retraction. There was no præcordial thrill, nor any pericardial friction-sound. The heart-sounds were free from murmur; the first being indistinct and feeble, the second somewhat duller than normal. The sounds were also at times reduplicated. This reduplication was intermittent and irregular, being wholly absent from certain beats, affecting only the second sound, or again presenting itself as a repetition of both cardiac sounds without any corresponding radial pulsation. The relations of this reduplication to the respiratory rhythm were difficult to determine. In the majority of beats it presented itself merely as a splitting of the second sound, and this occurred both with inspiration and expiration; and then, at irregular intervals, and this usually during inspiration, there was a reduplication of both sounds. The *deep area of cardiac dulness* extended from the lower border of the third interspace downwards to the sixth interspace, and from just within the left border of the sternum outwards to half an inch to the left of the nipple-line. The *pulse* was irregular in frequency, rhythm, and force, but without dichrotism or any quick, small beats (so often met with in cases of irregularity of mitral origin) corresponding with the reduplicated heart-sounds. There was moderate distention of the jugular veins, but no distinct collapse of these vessels attended inspiration.

During the early part of May there had been several rather alarming attacks of dyspnœa, with feeble and tumultuous action of the heart, which had subsided in a few hours; but on May 20 there was an attack of most threatening character, attended with terrible increase of dyspnœa, general venous congestion, lividity of face and hands, and extremely feeble, irregular action of the heart. The prompt administration of repeated large doses of digitalis and whisky seemed to rescue him from impending death; but it was two days before he recovered from the shock.

Fearing a repetition of such an attack, I determined to perform paracentesis, and on May 24, the patient sitting in a chair, I made a small incision through the derm over the sixth rib about 1½″ outside of the right nipple-line, drew the skin downwards so that the incision corresponded to the sixth interspace, and introduced a fine canula with a needle-point into the pleural cavity. An aspirator was attached to this (a small air-pump with a barrel holding about two fluidounces, and with a ball-valve so arranged in its nozzle that on being rotated in one direction by a little handle a communication is made between the canula and the barrel of the pump, while, when the valve is reversed, this communication is closed, and the barrel is connected with a lateral outlet, through which its contents can be forced by pushing the piston home). By gently working this, I succeeded in drawing off one hundred and sixteen (116) fluidounces of clear, pale, straw-colored serum without the entrance of any air to the pleural cavity. The effects of this were immediate and gratifying: the respiratory movements of the right side returned, and percussion became resonant down to the sixth rib. At this point the exhaustion of the patient compelled us to discontinue while yet there was evidently more fluid in the pleural sac (probably not less than thirty fluidounces). The right lung expanded promptly, and vesicular murmur with coarse, dry, crackling sounds was heard over the chest. The apex-beat of the heart returned to within the left nipple-line, but its position seemed comparatively little influenced by the withdrawal of so large an amount of fluid from the right pleural cavity. The canula was withdrawn, the incision closed by an adhesive strip, the entire right thorax surrounded by broad adhesive strips passing from the sternum to the spine, and the patient returned to bed, feeling relieved and easy.

Since that time—just one week—he has continued to feel much better. He eats well and sleeps comfortably. There has been no perceptible return of the pleural effusion, and the very slight effect of the operation itself upon his general condition may be judged from the following statement:

		Pulse.	Temperature.
May 24, at	8 P.M.	97 (regular)	100 3-5°
" 25,	12 M.	66 (intermitt.)	98 1-5°
" "	4 P.M.	64 (intermitt.)	99 2-5°
" "	8 P.M.	80 (regular)	99 1-5°

		Pulse.	Temperature.
May 26,	at 6 A.M.	73 (intermitt.)	98°
" "	12 M.	97 (regular)	99°
" "	6 P.M.	98 (regular)	99 1-5°
" 27,	6 A.M.	73 (intermitt.)	98°
" "	6 P.M.	86 (regular)	99°
" 28,	6 A.M.	75 (intermitt.)	98 1-5°
" "	6 P.M.	88 (regular)	97°
" 29,	6 A.M.	78 (intermitt.)	96 4-5°
" "	6 P.M.	86 (regular)	99 4-5°
" 30,	6 A.M.	75 (intermitt.)	98°
" "	6 P.M.	70 (intermitt.)	99°

I have placed him upon the use of iodide of potassium gr. v, with acetate of potassa gr. xv, thrice daily; and atropia gr. $\frac{1}{60}$, thrice daily, for its controlling action on the heart as well as for its diuretic power. I may add that careful percussion now shows that the area of hepatic dulness is materially decreased.

The evidence of a large effusion in the right pleural sac was clear enough here. The chest was too full to allow alterations in the patient's position to make much difference in the line of percussion dulness; but the dulness was of that peculiarly dead, flat type, with complete loss of elasticity, which is characteristic of large effusions, and rarely met with in mere consolidation of the lung. The vesicular murmur was absent over the dull area, and vocal resonance and fremitus were almost abolished. I do not attach so much importance to the auscultatory signs of large pleural effusions as to the other phenomena, since it happens often enough that vocal and respiratory sounds closely simulating those due to consolidation will be heard over the seat of the effusion, but due to transmission from the bronchi in the compressed lung. It is true that careful examination will usually detect their real origin; but no misinterpretation can well be placed upon the other signs, when we have the peculiar absolute flatness above referred to (often varying with altered positions of the patient's body), distention of the side with prominence of the intercostal spaces, and dislocation of the heart from pressure, all of which were present in this case. I have already mentioned an additional sign here detected, which is more rare: the sense of fluctuation detected by palpation in the lower intercostal spaces, or by percussing sharply on one finger placed over an intercostal space, while the other fingers are placed over the subjacent spaces to detect the fluctuation.

I will now invite your special attention to the signs furnished by the left side of the chest and the heart; and I believe that, after considering them, you will be inclined to think with me that our patient has both adherent pleura and pericardium. On questioning him closely, I find that in 1845, when he first suffered from symptoms of heart-disease, he had a severe attack of "inflammation of chest and heart," with much pain, which confined him to his bed for many weeks. Since then he has had several recurrences of severe pain about the heart and over the left thorax, with fever, and such general disturbance as to confine him to the house for several weeks. In the absence of any valvular lesion of the heart, this history certainly seems to point towards the occurrence of rheumatic pericarditis complicated with pleurisy. There are no friction-sounds now audible, but there are other reasons for adopting the view I have expressed. I do not think it likely that the heart would so closely follow the lung in its movements as to present a change in the position of the apex-beat from the sixth to the fourth interspace, unless there were adhesions between the pericardial and pulmonary pleura.

And again, the peculiar retraction of the lower intercostal spaces and of the epigastrium during inspiration, and that of the nipple attending the systole of the ventricles, are very significant signs of the presence of both pleuritic and pericardial adhesions. Add to this the positive increase in the area of cardiac dulness, without any valvular lesion, and note that this area is scarcely influenced by the stage of respiration. It is true that there is not the præcordial thrill which is felt in some cases of adherent pericardium, and that the moderately distended jugular veins present no collapse simultaneous with the diastole of the ventricles (which Friedreich has shown to occur in some cases of this lesion); but there are few conditions whose signs are more variable than this, and I believe that the phenomena which are here presented admit of no other satisfactory explanation. And I would suggest that it may be in consequence of the existence of such general pleuritic and pericardial adhesions that the pleural effusion has been limited to the right side, while on the left we find no evidence of free fluid in the pleural sac, but, on the contrary, the coarse, moist, crackling râles of congestion and œdema of the lung-tissue. I have on a good many former occasions had the opportunity of observing how, when a cause predisposing to general dropsy exists, and while one lung is free from adhesions, the other is tightly adherent, free serous effusion takes place on the one side, and is represented on the other by œdema of the lung-tissue and of the pleuritic adhesions.

I will, before speaking finally of the operation of paracentesis itself, allude to the bearing which its results had upon the diagnosis of this case. In the first place, the character of the fluid withdrawn was entirely in favor of the view that the hydrothorax was passive and not inflammatory in its origin. The canula encountered no difficulties from false membranes, no floating flocculi of lymph arrested the escape of liquid from time to time, and the fluid itself was singularly clear, light-colored, and free from spontaneously coagulable elements. All these points mark the difference between simple dropsical effusions in the pleura and those which depend upon inflammation of the membrane. Again, the withdrawal of the fluid enabled us to demonstrate what could not be definitely determined before, owing to the simultaneous presence of ascites and hydrothorax,—that the liver has undergone contraction, which, of course, is the most conclusive evidence in favor of the view that the initial lesion in this complicated case was *cirrhosis of the liver*.

The indications for the operation which has been performed here merit a moment's attention. It is unfortunately true that it can be regarded in this case as a palliative measure merely, and by no means as expected to permanently relieve the hydrothorax. There is, indeed, every reason to fear that, when a constant and probably incurable cause exists for the

production of the dropsy, it will but too surely and speedily recur. As a consequence, it would seem but proper to require the presence of far more urgent indications for paracentesis in such instances than would justify its performance in cases, as of subacute idiopathic pleurisy, where we might hope that it might effect a cure. It is of course difficult to formulate the principles which must guide us as to the use of this operation, but I would suggest the following rules as sanctioned by eminent authorities and approved by my own experience. In cases of simple pleuritic effusion, reaching up to the second or third interspace, so long as no urgent interference with respiration or circulation occurs, the operation should not be resorted to until a faithful and prolonged trial has been made with internal remedies and external applications to promote the entire absorption of the fluid. In case such treatment proves unavailing, and either the effusion begins to increase or the patient's strength begins to fail seriously, the operation is *justified*. In case evidences of the occurrence of purulent discharge from the pleural surface, gradually converting the hydrothorax into an empyema, should present themselves, the operation is usually *called for*, without regard to the presence of urgent symptoms of respiratory or circulatory embarrassment. In cases where the hydrothorax is due to some mechanical or at least non-inflammatory cause, as often happens in renal, hepatic, and cardiac disease, there is but little danger of the development of empyema, and the indications for paracentesis are based exclusively upon the interference with the action of the lungs and heart caused by the effusion. Whenever, finally, from whatever cause the hydrothorax proceeds, the amount of effusion has increased until respiration and circulation are constantly and alarmingly disturbed, as shown by rapid, feeble, irregular pulse, œdema of the feet, hurried, shallow breathing, lividity of the face and hands; or whenever, no matter what the *constant* amount of such disturbance may be, there are occasional paroxysms of violent dyspnœa, with great irregularity and weakness of the heart's action, the performance of paracentesis is imperatively demanded. I say this because, in such cases of extensive pleural effusion, sudden death is by means uncommon, and such patients live in constant danger of a rapid increase of the effusion to a fatal extent, or of an unusually violent paroxysm, in which the fatal result may occur.

You will remember how alarming was the attack which this patient suffered on May 20; and you will readily perceive the extreme danger that a repetition of such a paroxysm would have proved instantly mortal. Having failed to afford him any material relief by internal medication, I did not feel justified in exposing him to such danger, and therefore tapped his chest so soon as he had sufficiently reacted from the paroxysm. The operation itself is a very simple one. The effects of the entrance of air into the pleural cavity have doubtless been exaggerated; but still, in all cases where there is reason to believe that the effusion is merely serous, it is desirable to withdraw the fluid without permitting such a result. And this can be readily effected by puncturing the chest-wall with a needle-pointed canula furnished with an india-rubber tube, by means of which the effusion can be conducted below the surface of water in some suitable vessel, and thus allowed to escape without the possibility of air entering. Or we may secure the same results by the use of Bowditch's syringe, or the aspirator, both of which work on the plan before described. The rate at which the fluid is withdrawn must vary with the character of the fluid, and the condition in which the lung is supposed to be. If the collection is a purulent one, it had better be withdrawn through a quite large canula; since it will probably be necessary to insert a canula to be worn continuously for some time. If the effusion be serous, but the result of active inflammation, it should be drawn off through a very fine canula, so that the lung which is, in all probability, bound down by adhesions, may gradually expand and fill the space left by the fluid; for, if this be withdrawn too rapidly, there is such strong suction that it is difficult to prevent the entrance of air along the sides of the canula into the chest. In cases such as the present, where the effusion is the result of a passive dropsy, the lung is in all probability free to expand, and the fluid may safely be withdrawn, as I did it, with moderate rapidity and through a medium-sized canula.

There is no after-treatment required in such operations. The table of the pulse and temperature of this patient during the week immediately succeeding the tapping shows how little constitutional disturbance follows its performance. In the present case I surrounded the right thorax with strips of adhesive plaster, to prevent the ribs from expanding more freely and rapidly than the compressed lung could be inflated, and I certainly succeeded in securing the withdrawal of a large quantity of fluid and very free expansion of the lung without the production of any pneumothorax.

The tendency to a return of the effusion after paracentesis varies infinitely with the cause, the condition of the pleura, the constitution of the patient, and the mode of performance. I cannot, at this time, attempt to discuss the details of this point, particularly as our patient illustrates the fact that in not a few cases the urgency of the symptoms compels the performance of the operation without reference to the liability of the return of the effusion. Unfortunately, I cannot hope for a long respite from this result in the present case; but, even if the serum reaccumulate in the course of some weeks or months, the operation will have been successful in affording him marked temporary relief, and freedom from the danger of sudden and painful death.

Postscript, June 10.—Up to the present date, seventeen days after the operation, the same marked relief continues; the heart's action is slow (65 to 70) and more regular. The effusion has certainly increased, but only to a slight degree; and the patient is able to walk about quite freely, and has even left the hospital on a pass; though he is easily over-fatigued.

ORIGINAL COMMUNICATIONS.

ABSCESS OF THE LARYNX IN YOUNG CHILDREN.

BY JOHN S. PARRY, M.D.,

Attending Accoucheur to the Philadelphia Hospital, Vice-President of the Obstetrical Society of Philadelphia, etc.

THE term abscess of the larynx is used here, not because the writer believes it to be entirely appropriate to the condition which it is proposed to describe, but simply for the want of a better name. The disease to which it is applied is a rare one, and, so far as the writer is aware, the peculiar train of symptoms accompanying it have never been described, unless, indeed, it has been mistaken for retro-pharyngeal abscess. Two cases have come under my notice, one of which terminated in recovery, the other in death. Both occurred in the wards of the Philadelphia Hospital.

Case I.—John I., aged 4½ months, a negro, well nourished, and wet-nursed by his mother, who is a healthy woman. On my visit to the ward on Tuesday morning, she called attention to the child, stating that he had been irritable and cross for two or three days. He had not nursed well, though she did not observe any difficulty in swallowing. During the preceding day he had suffered from difficulty in breathing, with noisy inspiration, and total inability to swallow.

At the time of the examination he was lying upon his mother's lap, with his head thrown back. The muscles of the back of the neck were rigid. His eyes were prominent. Respiration was exceedingly laborious, and was attended with vigorous movements of the alæ nasi. Inspiration was long, difficult, and stridulous. During inspiration the base of the thorax was surrounded by a transverse constriction. This disappeared during expiration, which was easy and noiseless. The voice was almost whispering, and his cry almost suppressed. The dyspnœa was so great as to prevent any attempt at crying or moving. His whole object was to breathe. He had no cough. The larynx was thrust forward so as to form a decided tumor in the neck. The anterior margin of the thyroid cartilage was sharply defined. There was some swelling upon either side of the larynx, at the posterior margin of the thyroid cartilage. It did not fluctuate. The examination gave rise to pain and uneasiness, but did not increase the dyspnœa. The boy was totally unable to nurse or to swallow either fluids or soft solids.

The chest was resonant on percussion. No râles could be heard in any part of it. The respiratory murmur was scarcely audible.

His tongue was furred, and the mouth filled with mucus. A careful inspection of the pharynx revealed no disease, and an examination with the finger showed that there was not a retro-pharyngeal abscess. The epiglottis and parts around were examined with the finger and did not appear to be œdematous. This greatly increased the dyspnœa, and nearly cost the child his life.

The patient was carefully watched, with directions not to allow him to die without the operation of tracheotomy having been performed. Warm poultices were applied to the throat to favor suppuration, under the impression that there was an abscess behind the larynx.

During the succeeding two days his condition did not improve. The prominence of the larynx increased, while the swelling extended from behind forwards. At this time it was thought that there was slight fluctuation near the median line, over the thyroid cartilage. An incision was made from the superior to the inferior margin of this, directly in the median line, and nearly two fluidrachms of thick yellow pus flowed out. The larynx immediately receded, all swelling disappeared, the intense dyspnœa and dysphagia ceased at once. From that moment recovery commenced, and the boy did not have a single symptom of disease afterwards.

Case II.—J. G., aged 9 weeks, was born in the Philadelphia Hospital. Immediately after labor his mother suffered from puerperal fever. The child was healthy when born, but when less than a week old he was attacked with erysipelas of the buttocks, which gradually spread upward until the whole of the body and head were affected. This was followed by an abscess situated over the upper part of the occipital bone, near the posterior fontanelle. The contents of this were withdrawn by the aspirator twelve days before the present disease began, and again ten days before. The abscess immediately refilled, and it was opened with a knife three days ago. The erysipelas exhausted the child greatly, but during the last month he has been improving.

The present illness began suddenly ten days ago, with what the mother calls "wheezing in his throat." This was accompanied by some swelling about the larynx, and some noise in breathing. These symptoms continued until last evening, when the mother called Dr. Stone's attention to the child for the first time.

Present condition.—He is poorly nourished, but his general appearance is better than would be expected in an infant who had been so long and so seriously ill. His face is pale; the vessels of the neck and scalp are distended. He lies with his eyes half closed and his head thrown back, as in commencing opisthotonos. The muscles on the back of the neck are rigid and tense.

The alæ nasi move rapidly in breathing. The external muscles of respiration are called into use, those of the neck acting violently. The sternum is arched forward. During inspiration the convexity of this bone is increased, and a deep gutter appears around the base of the chest, on a line with the ensiform cartilage. During expiration this disappears, so that the thorax is actually larger during the expiratory than during the inspiratory act. The breathing is irregular, from forty to fifty times per minute. Inspiration is extremely difficult, is prolonged, and is attended with a sharp stridulous sound which can be heard all over the ward. Expiration is easy and noiseless. The child coughs but little. The sound is hoarse, broken, and tends to become whispering. The cry is nearly suppressed, but the aphonia is not quite complete.

The thorax is everywhere resonant on percussion, and auscultation reveals no evidences of disease of the lungs. The respiratory murmur is inaudible. The laryngeal sound is heard by transmission over the whole of the surface of the chest.

Physical examination of the pharynx reveals no tumor. The finger passes down behind the larynx. The epiglottis can be distinctly felt, and there seems to be a little puffiness upon either side of its base. The examination produced much uneasiness, and was followed by profound dyspnœa.

The larynx is thrust forward so as to produce a decided prominence on the anterior surface of the neck. There is some swelling just over the posterior margins of the thyroid cartilage. No fluctuation can be detected. The examination causes pain.

The tongue is furred, the mouth filled with dense opaque mucus, stomach irritable, and bowels constipated. He has considerable difficulty in swallowing, and cannot nurse at all.

The pulse is weak, irregular, and from 140 to 160 per minute. The irregularity occurs during inspiration.

He continued to grow worse during the succeeding night, and died the next day of dyspnœa.

Post-mortem.—The pharynx was perfectly healthy. The larynx was removed with the tongue and upper part of the trachea. The anterior aspect presented the following appearances: In the middle line and a short distance to either side, bounded by the inner border of the sterno-thyroid muscles, there was distinct fluctuation. Posteriorly to the outer margins of the same muscles, and upon either side, were other fluctuating swellings. The two projections communicated, and an impulse was transmitted from the surface of one to all the others.

The epiglottis was erect, thin, and pale. The cavity of the larynx was nearly obliterated; it contained no false membrane, and the mucous membrane was pale and healthy. Immediately without the epiglottis, between its base and the superior inner margin of the thyroid cartilage, were two fluctuating swellings, one upon either side. These compressed the epiglottis so that its lateral margins were nearly in contact and likewise nearly obliterated the rima glottidis. Fluctuation was communicated from these swellings to those on the sides and the centre of the anterior outer surface of the organ.

Upon making an incision in the median line, over the prominence of the thyroid cartilage, more than two drachms of thick yellow pus flowed out. The fluctuating prominences on the exterior and interior of the larynx immediately collapsed, and the cavity of the organ was restored to its natural size. A probe could be passed through the incision backwards, and around the posterior margins of the thyroid cartilage, upon either side, so as to put the mucous membrane of the interior of the larynx upon the stretch at any point.

The perichondrium was separated from the thyroid cartilage upon both its inner and outer surfaces. Both surfaces of the cartilage were eroded and rough, while its tissue was softer than it is when healthy. The cricoid cartilage was perfectly healthy. The other organs of the body were healthy.

These two are the only examples which I have met with of what must be a rare disease of the larynx in children. Only one author upon the diseases of children, whom I have consulted, has anything to say upon the subject. This is Vogel,* who speaks of "abscesses of the larynx" as a complication of typhoid fever in children. He states, however, that he has never met with an example of the disease. His description of the symptoms is very vague, and is not sufficient to warrant us in concluding that he alludes to the condition which has been described. Niemeyer† and Wood‡ speak of a somewhat similar condition under the name of "Laryngeal Perichondritis," but neither author details the symptoms with sufficient care to make the diagnosis easy. Porter§ has a chapter on "Abscesses around the Larynx," and Rühle‖ describes the condition in adults, but has nothing to say about abscess of the larynx in children.

In both of these children the symptoms were well marked, and could not but attract the notice of even a careless observer. The terrible dyspnœa, the distressed face, the dysphagia, the stridor, which could easily be heard over a large room, immediately attracted attention. It is not at all improbable that some of the cases recorded as post-pharyngeal abscess have really been abscess of the larynx. In certain particulars the symptoms of the two diseases are strikingly alike. In both there is dyspnœa with dysphagia, and, according to Fleming,¶ Allin,** West,†† Vogel,‡‡ and Smith,§§ there is retraction of the head. Relying upon the rational symptoms alone, retro-pharyngeal abscess would probably have been diagnosticated in both of the children whose histories have been related in this paper; but upon making a physical examination of the pharynx, no swelling could be detected in the locality in which this variety of abscess usually projects. This will at once enable the physician to distinguish between the two diseases, while the projection of the larynx anteriorly with induration at the posterior margin of the thyroid cartilage would direct attention to the larynx.

In both cases the symptoms resembled those of œdema of the larynx in adults. The physical examination likewise enabled us to exclude this; for the epiglottis could be felt, thin and healthy, below the root of the tongue. Besides, œdema glottidis is observed "almost exclusively among grown persons."‖‖‖ It is doubtful whether it can occur in children as young as these. Moreover, œdema is attended with violent paroxysms of suffocation, such as occur in croup and other laryngeal diseases. In both these children the intensity of the symptoms was steadily progressive from the commencement of the inflammation until the recovery of the one and the death of the other.

Pseudo-membranous laryngitis is another disease which the one we are discussing resembles. They have in common an insidious beginning, are both attended with great dyspnœa, stridulous breathing, and contraction of the base of the chest during inspiration. But in pseudo-membranous laryngitis the head is not thrown back, the dysphagia is absent, the larynx is not thrust forward, and there is no induration at the posterior margins of the thyroid cartilages. In both of the histories which have been related in this paper it is specially noted that expiration was not difficult, and was noiseless. Jacobi, of New York, in an able paper on croup¶¶ has called attention to the fact that in that disease both inspiration and expiration are impeded. Since our attention was directed to this as a diagnostic sign of pseudo-membranous laryngitis, we have not met with a single exception to the rule; and, unfortunately, the wards of the Philadelphia Hospital have furnished a number of opportunities to verify the diagnosis by a post-mortem examination.

Meigs and Pepper*** attach much importance to the depression or sulcus about the base of the chest in true croup. This is of no value whatever in dis-

tinguishing the disease which is being described from pseudo-membranous laryngitis. We have never seen the symptom more marked in fatal cases of that disease than it was in both of the children whose histories have been related.

In relation to the nature of the affection we have but little to say. Whether it commences as inflammation of the perichondrium or the sub-mucous cellular tissue is uncertain. It is hardly the latter, for the same reason that œdema of the glottis is rare in infants.

Treatment.—The prognosis of this disease of the larynx is evidently very serious, and to save the patient the treatment must be prompt and efficient. As soon as it is suspected, the child must be carefully watched. In the first case a free incision from the upper to the lower margin of the thyroid cartilage was followed by instantaneous relief and complete recovery. In the second the same result would probably have followed if we had boldly plunged the bistoury in. If the abscess can be opened in the median line, it should be done; and if not, the incision must be made upon a line with the posterior border of the thyroid cartilage, though it is true that in this locality some care has to be exercised, as the incision has to be made close to large vessels.

If this does not give relief, only one course is open,—that is, to perform tracheotomy, with the hope that the life of the patient may be prolonged until the pus is discharged. Any one who has seen a case of this kind can have no doubt in regard to the propriety of such a proceeding.

It is not difficult to conceive that this operation might be demanded in the latter stages of the disease and after pus had been discharged on account of the serious disease of the thyroid cartilage.

TRANSLATIONS.

ON THE RADICAL CURE OF CERTAIN FORMS OF LACHRYMAL TUMOR BY MEANS OF PARTIAL EXCISION OF THE SAC, METHODICAL CATHETERIZATION, AND INJECTIONS OF THE SULPHITE OF SODA.

BY DR. MONOYER,

Professor *agrégé* of the ancient Faculty of Medicine of Strasbourg, in charge of the course and of the clinique of ophthalmology in the Faculty of Medicine of Nancy.

Translated by Dr. H. Culbertson, of Zanesville, Ohio, from the *Archives Générales de Médecine*, January, 1873.

NOTWITHSTANDING the multiplicity of modes devised for the cure of lachrymal tumor, and the incontestable progress realized by Mr. Bowman, in 1857, in the surgical therapeutics of this form of ocular disease, lachrymal tumor continues none the less to discourage some practitioners, from the duration, and in many cases the inefficacy, of treatment. Only those who have kept their patients in view for a considerable time can say how many permanent cures they have obtained, and above all how many cures with re-establishment of the lachrymal passages; successes are still more rare when the cases are chronic and complicated.

Among complications there is one particularly rebellious to treatment: we refer to relaxation of the sac, with or without hypertrophy of its walls. Authors recommend, almost exclusively, compression to overcome dilatation of the sac; but I do not know that this mode has ever succeeded, at least when the anterior wall is considerably hypertrophied. We have been so fortunate as to obtain in two cases of this character, by the aid of a proceeding entirely different from that which has just been indicated, a double success, equally remarkable for the brevity of the treatment and for the perfection of the final result. Accordingly, we shall, we believe, be of service both to science and to the sick, by reporting in all their details the histories of the cases in question. We will follow our narrative with certain reflections adapted to make apparent the points which constitute the new part of the treatment employed under these circumstances.

Case I.—*Lachrymal tumor with dilatation and hypertrophy of the walls of the sac (hypertrophic dacryo-cystectasis); stricture at the inferior orifice of the nasal canal; partial excision of the sac; methodical catheterization by the incised superior lachrymal canal; injections of the sulphite of soda; rapid and radical cure, with re-establishment of the natural passages.*

Rosine B., born and living at Baccarat (Meurthe), aged 38 years; married; without occupation; of good constitution, and of nervous temperament; presented herself, February 4, 1867, at the ophthalmic clinic of the faculty of medicine of Strasbourg, to be cured of a lachrymal tumor.

History.—The patient has always enjoyed good health; she has been affected, since childhood, with lameness of the left leg; there is deformity of the hip of the same side. She menstruates regularly every three weeks, and has never borne children. Two years since she observed a tumor at the inner angle of the left eye; small at first, it has constantly increased in size. At first it was possible, by compressing it with the finger, to make it disappear entirely, even for several days, its liquid contents escaping by the nasal canal into the nasal fossæ; but for four months past it has been impossible thus to completely empty the tumor. Its development was preceded by epiphora.

The patient has been treated on various occasions. Dr. Mouginot, of Lunéville, gave her, one year since, by the inferior lachrymal punctum, and with an Anel's syringe, injections of tepid water, which the patient's husband, a glass-maker, learned to administer with great dexterity, and with which he persevered for some time, but without success. Injections of nitrate of silver, in aqueous solution, were no more efficacious, and had no other result than to induce inflammation of the tumor. An injection of Labarraque's solution, *undiluted*, made three months ago, under the advice of another practitioner, was also followed by intense inflammation, accompanied with acute pain. From this date the contained liquid which escaped from the tumor when it was compressed had a most fetid odor and taste, nor did injections of Labarraque's solution, diluted with water, which were subsequently employed, suffice to remove its offensive character; the epiphora continued incessantly. In the mean time the patient came to Strasbourg.

Present condition.—Immediately below the internal angle of the left eye, the skin, which is slightly red, is raised up by a tumor of the form and size of a medium-sized hazel-nut, and a little elongated. The tumor measures in its greatest length about one centimetre and a half, and its breadth is one centimetre; its great axis is not vertical, but follows the course of the lower border of the orbit. By pressing with the finger in a

direction from above downwards, it is possible to partially empty the sac, which is made evident by a very notable diminution in the tension of its walls; but the tumor does not entirely subside, and continues of the same apparent volume; the contents, which are made to flow out by pressure, escape by the nasal canal into the corresponding nostril, and thence into the pharynx, where, in consequence of their fetid character, they disagreeably affect the taste and smell of the patient. If, during these pressure-manœuvres, a drop of muco-pus sometimes flows backwards through the inferior lachrymal punctum, nothing whatever passes by the superior.

On touching with the index finger the tumor, previously emptied as much as possible, there is felt the sensation of a small body, having the form and consistency of a tarsal cartilage, beginning on a level with the entrance of the nasal canal and extending along the orbital border more than a centimetre; its thickness vertically is estimated at not less than two millimetres; its dimensions in an antero-posterior direction cannot be determined. This body seems to extend backwards, becoming gradually thinner, and to be attached to the osseous wall of the orbit; its mobility, however, is considerable.

Refilling now the lachrymal sac gradually, by the aid of an Anel's syringe, I continue to perceive the small body at the inferior part of the tumor, forming, so to speak, an integral part of the walls of the sac itself, until the excess of tension, the result of the too great accumulation of liquid (55 divisions of Pravaz's syringe could be injected), prevents the depression of the tumor, and thus hinders palpation. Anel's probe can be passed into the tumor through either lachrymal punctum, but cannot be made to penetrate more than two centimetres, at which depth there is felt a membraniform obstacle; by sounding in all directions the absence of caries is determined. The probe appeared to pass behind the little body we have described, which was composed of nothing more than the folds formed by the superior and inferior walls of the lachrymal sac, considerably hypertrophied and brought closely together by the pressure of the finger. If I lay great stress upon the sensation of a foreign body perceived in our patient, it is because, not being mentioned by any author, it might give rise to an error in diagnosis; for us, on the contrary, it indicates relaxation with hypertrophy, more or less marked, of the walls of the lachrymal sac, as we were able to determine during the operation.

On February 6, I made through the inferior punctum an injection of the sulphite of soda in solution, 1 to 200: from the following day, even, the secretion of the sac was entirely modified in respect to its plastic properties; it had lost its bad taste and fetid odor.

Treatment.—The choice of the treatment to be instituted in this particular case was very embarrassing. To adopt catheterization as performed by Bowman, or even with the aid of compression of the sac, was to undertake a mode of practice the issue of which seemed very doubtful, and which would require the patient to remain a long time at Strasbourg; to proceed to the obliteration of the sac was to have recourse at once to an operation which, in our opinion, should be reserved as a last resource, to be employed in despair when other means have failed. We decided to attempt a new method, and to excise a portion of the hypertrophied sac.

The 8th of February having been fixed for the operation, it was performed in the presence of our colleague and friend Dr. Munch.

The patient having been profoundly chloroformed, I incised with a small bistoury the skin which covered the tumor, to the extent of two centimetres and a half; the incision, commencing at the superior extremity of the tumor and immediately below the tendon of the orbicularis, was directed from above downwards and within outwards, following thus in a straight line the direction of the great axis of the tumor, and nearly also that of the muscular fibres of the orbicularis muscle.

The external integument having been divided, I separated with the point of the bistoury the fibres of the orbicularis, and came directly upon the sac; I dissected the tumor carefully on each side of the incision, at all points accessible to my instruments; the anterior wall was thus exposed below, as well as inwards as far as the orbital border, and above to a corresponding depth.

To facilitate this first part of the operation, I had previously injected water into the lachrymal sac, so as to distend it to the utmost; I had, moreover, introduced Anel's probe through the superior punctum. The sac having been cleared, I incised the anterior wall in its entire length, and in a direction parallel to the external incision; by the opening thus formed, there escaped a large quantity of thickened ropy mucus, intermingled with a little thin pus.

The walls of the sac were on their internal surface of a well marked slate-colored hue, and were considerably thickened.

Catheterization practised through the wound, with Bowman's probe No. 2, showed that the nasal canal was pervious in its entire length, except at its lower part, where there was a contraction of the membranous orifice, which, however, was easily overcome.

With scissors curved upon the flat, a part of the sac was now excised: two slips, nearly three millimetres wide in their middle portion and narrowed at their extremities, were thus removed from the sides of the incision. The bleeding, which was quite free during the operation, yielded quickly to sponging with cold water.

The interior of the sac and of the lachrymal passages was carefully cleansed by means of the solution of sulphite of soda, injected with Anel's syringe armed with a large-sized canula; then the wound was closed by means of three sutures, including upon each side the skin and walls of the sac. Lastly, the superior lachrymal canal was incised with a Weber's knife, to facilitate future catheterization. Cold applications were applied to the wound.

[The wound after uniting opened, but subsequently healed under the influence of injections of the sulphite of soda. The nasal duct was kept pervious by catheterization. On the eighteenth day the patient left the hospital with the wound completely healed. The husband of the patient injected the solution and catheterized the nasal duct at intervals for some time after she was discharged.—TRANSLATOR.]

March 21, 1867, I presented my patient to the Medical Society of Strasbourg. The report of the *séance*, after having given a résumé of the case, adds, "The members of the Society verify the absence of all deformity; the small cicatrix resulting from the operation is scarcely visible."*

[October 20, 1871, the patient was heard from by letter, and, as the disease had not returned, the cure remained complete.—It is unnecessary to give the particulars in the second case of the operator, which was equally successful in its results with that just narrated. —TRANSLATOR.]

Remarks.—One fact strikes us at once in the above cases,—viz., the rapid recovery. In the first case eighteen days sufficed to obtain a radical and permanent cure, and *with re-establishment of the natural passages*, of a lachrymal tumor of at least two years'

* *Gaz. Méd. de Strasbourg*, April 25, 1867, No. 8, p. 103.

standing and complicated with hypertrophic dilatation of the sac; in the second case the same result may be considered as having been obtained also in eighteen days, for the subsequent injections, which were continued a week longer, served only as an additional measure of precaution.

In regard to the operation to which we owe the above-narrated successes, it offers two interesting peculiarities to which we must direct attention: — 1st. As to the operative procedure, *we excised a part of the sac* which was notably thickened by hypertrophy of its connective tissue and epithelium; we thus succeeded in diminishing the volume and dimensions of the sac better and much more rapidly than could have been done by compression. 2d. In regard to the consecutive treatment, we had recourse to *injections of sulphite of soda*, which have the double advantage of stimulating the vitality of the tissues and of removing instantaneously the fetid odor of the matter secreted by the mucous membrane of the sac.

Partial excision of the sac is not absolutely a new operation; it has, however, very seldom been tried with the view of overcoming the dilatation of the sac.

Von Ammon is the only author, to our knowledge, who has published two cases *of cure of dilatation of the lachrymal sac* (dacryo-cystectasis of Hasner) *by the removal of a flap of its anterior wall.* These two cases are published in an article entitled "Ophthalmological Sketches," which appeared in 1851,* and which has been translated by M. Bénard, in the *Annales d'Oculistique* for 1852, vol. xxvii. We derive from the last-named work the account of the cases in question. [It is not thought necessary to give the details of these cases.—Translator.]

Von Ammon performed these operations with the object, he said, of diminishing the cavity of the lachrymal sac, and of thereby increasing its contractility; by removing the anterior wall at the point where the mucous membrane formed folds, he moreover desired to prevent, or at least to diminish, the secretion of the morbid material which accumulated in the sac, by inducing, through the irritation caused by the introduction of suture-pins, a modification of the diseased mucous membrane."

For our part, we believe the Dresden ophthalmologist was right; but when he published his observations in 1851 he had changed his opinions upon this matter, adopting the ideas advanced the previous year by M. de Hasner in a work upon the "Physiology and Pathology of the Lachrymal Apparatus:"† he believes with the Prague professor that in *dacryo-cystectasis* or *mucocele* there was always found a partial obliteration of the calibre of the nasal canal, and that dilatation of the sac could only be made to disappear by rendering general the adhesion which was previously but partial. Von Ammon therefore considered it very probable that he owed his two successes to the complete or at least very general adhesion of the membrane lining the lachrymal sac,—adhesion due to the twisted suture of Dieffenbach, employed by him in his operations.

As the Dresden surgeon did not seek in any way to assure himself whether under these circumstances the natural outlets for the tears did or did not preserve their permeability, and as on the other hand partial excision of the sac was not followed by any treatment suited to prevent contraction of the nasal canal, it is difficult to determine in what manner the recovery was obtained,—whether the natural passages were re-established, or whether they were entirely obliterated.

Nevertheless, we should be strongly disposed to see in the first case related by Von Ammon a recovery with re-establishment of the natural passages, while, on the contrary, the second operation appears to have ended in occlusion of the sac: such at least is the impression we have from the account of the phenomena following the operation.

Mr. Critchett, in his "Lectures upon the Diseases of the Lachrymal Apparatus," says, in speaking of the treatment of lachrymal tumors where the sac is augmented in volume at the same time that its walls are hypertrophied, "Once or twice Mr. Bowman has found it well to remove, by dissection, the anterior wall of the sac: there is no objection to be made to this procedure save its tediousness and difficulty."‡

Our own observations, as well as those published by Von Ammon, are such as to show how little foundation there is for the objection advanced by Mr. Critchett against partial excision of the sac; this operation in reality presents nothing particularly tedious or difficult to execute.

To sum up, two cases published by Von Ammon, and one or two mentioned by Critchett as belonging to Bowman,—such is the list of partial excisions of the sac found in the annals of science previous to our own operations.

If we consult classical authors, we find that almost all are silent as to this operation; M. de Wecker, at most, merely mentions it in the second edition of his "Treatise on Diseases of the Eyes," vol. i. p. 896 (1868), to express his preference for compression aided by injections.

Mr. Critchett, after having recalled that Bowman had had recourse, once or twice, to partial excision of the sac, adds, "I have instead sometimes opened the sac freely, and applied to its interior the potassa cum calce, so as to destroy a considerable portion without injuring the skin."§

M. Warlomont, in the "Dictionnaire Encyclopédique des Sciences Médicales," says (in the article entitled "Surgical Pathology of the Lachrymal Passages"), in speaking of the treatment of *mucocele*, "If the sac be very much distended, *we may*, after having opened it, remove a portion with scissors."‖

It seems to us superfluous to remark that partial excision of the sac should not constitute a general procedure applicable to all forms of lachrymal tumor. The number of cases in which this mode of treatment can and should be practised is indeed so limited that in a period of five years we have had recourse to it but twice. In the course of the year 1871, we thought for a moment that we had to do with a case which would justify the operation of which we speak: there was a lachrymal tumor with relaxation and thickening of the walls of the sac and a diverticulum upon the orbital plate, but, the sac being opened, we perceived the mucous membrane covered with numerous granulations: this annoying complication, which we had not been able to foresee, rendered it evident that all efforts to re-establish the natural passages would fail; we did not hesitate to proceed at once to the obliteration of the sac by cauterization with pencils of Canquoin's paste. Partial excision of the sac, we believe, is not indicated, except in simple or hypertrophic *mucocele*, and especially in the latter any complication such as caries of the bony parts, or an incurable affection of the mucous membrane (for example, granulations), constitutes an insurmountable obstacle to the re-establishment of the natural passages, and calls for other treatment.

Let us also add that excision will not, in general, suffice in itself to cure a lachrymal tumor, and that it seems to us necessary to follow this operation by methodical cathe-

‖ Dict. Encyclop. des Sciences Médicales, 2d sér., t. i. p. 59, 1868.

terization and by injections of the *sulphite of soda*. It is the union of these three therapeutic remedies which has procured for us the successes related above, and which constitutes the novelty of our mode of treatment. One word, finally, upon the use of the *sulphite of soda* in ocular therapeutics. This medicine acts at once as a disinfectant, an antiseptic, and as an alterative to the tissues, the vitality of which it arouses. The case which we reported in the beginning of this article demonstrates the utility of sulphite of soda injections in checking the morbid hypersecretion of the mucous membrane of the lachrymal sac, in modifying its nature, and in instantaneously removing from it all nauseating odor.

These same injections may be advantageously substituted for astringent injections in the treatment of different affections of the lachrymal passages. The solution of sulphite of soda, applied with a brush to the palpebral conjunctiva, has also rendered us good service in the treatment of *trachoma*.

In employing this as a topical remedy, we gradually increase the strength of the solution; as 1 gramme to 200 of distilled water, 1 to 100, 1 to 50, and even 1 to 30.

The conjunctiva painted with the solution 1 to 30 bleeds readily, if the application of the remedy be at all prolonged.

In other forms of disease than ophthalmic, the sulphite of soda, in solution or in ointment, also gives excellent results whenever it is necessary to excite the vitality of the tissues threatened with mortification, as in carbuncle, wounds of an unhealthy character, atonic ulcers, etc.

Treatment of Pernicious Malarial Fever.—In the *Southern Medical Record* for May, 1873, Dr. Benj. Rhett, of South Carolina, has a paper upon Congestive Malarial Fever, in which he says, "In most cases of fever, intermittent or remittent, twenty grains of quinia, administered during the intermission or remission, are sufficient to arrest the next paroxysm. But the same quantity, twenty grains, administered during a paroxysm, has no control over that paroxysm, either during the cold or hot stage, but exercises its influence, if it has any effect at all, on the succeeding paroxysm. Indeed, the febrile symptoms are aggravated by giving quinia during the paroxysm.

"Suppose, now, we administer during the paroxysm, either during the cold or hot stage: ℞ Morphia, gr. ¼; chloroform, teaspoonful; camphor, gr. ii, and repeat if necessary—the effect of the remedy is not only to *abort the chill*, but to *shorten the febrile paroxysm* by several hours. The same remedy administered previous to the hour of chill will sometimes postpone the attack several hours, and sometimes prevent it altogether."

He also reports several cases, of one of which he writes as follows:

"I arrived about five o'clock in the afternoon, and found him in the following condition: His surface pale, with cool extremities and cold nose; features pinched, and finger-nails blue; the pupils of his eyes contracted to the size of a pin's head, and little sensible to variations of light. Soon the surface grew warmer, but the face, especially the nose and lips, became purple with venous congestion; the surface was soon bathed in profuse perspiration; the skin of the hands and feet became shrivelled, the nails being of a purple color,—the semi-comatose condition continuing. His breathing was embarrassed and stertorous, and there was considerable difficulty in swallowing. When partially roused to take medicine, his face had a wild, stupid glare, and he would relapse again into stupor with the spoon in his mouth. Having neither chloroform nor camphor with me, I administered one-fourth of a grain of morphia and twenty drops of turpentine every hour, plunged his feet into warm water, placed sinapisms upon legs, thighs, and arms, and hot flannels, with turpentine, around the abdomen, and gave turpentine enemata. When chloroform and camphor were obtained, he took, every two hours—morphia, gr. ¼; chloroform, teaspoonful; camphor, gr. ii. This treatment was persevered in from five o'clock in the afternoon of the 13th of July to seven o'clock A.M. of the 14th, when there was a return to consciousness,—a subsidence of stupor. A flow of urine, which had been suppressed, took place, and a subsidence of fever occurred. Quinia was given in full doses, and the patient soon rallied."

How to Test Milk.—To prove the properties of milk, certain tests are useful. Those of Vogel are explicit and concise, viz.:

1. Fill a graduated galactometer with milk, let it stand covered for twenty-four hours, then the cream should at least comprise three lines of the glass in thickness.
2. Test with blue and yellow paper.
3. Taste, which should be insipid and slightly sweet.
4. The microscope.

"If nurse has been confined more than eight days, colostrum corpuscles and epithelial cells should not be present at all, or in small quantities, milk-globules of unequal size or too many." "In pure milk," says M. Donne, "nothing but milk-globules are seen." The same writer also shows human milk to be alkaline. I have not been able to find any reported case of acidity in human milk.

Unhealthy milk may be inferred from its scarcity of cream, change in color and taste, generally slight, but principally from microscopic examinations.

In 1853 Vogel first discovered vibriones in human milk. There was no fermentation, as the milk was alkaline. The child had all the appearances produced by malnutrition. From 1854 to 1861, Dr. Gibb, in an examination of many hundred specimens, found two genera of animalcula in the milk of women in whom the general health was disordered during lactation, or in whom lactation was prolonged or an insufficient quantity of milk secreted. He also found, in all periods of lactation, milk varying in color, sp. gr. 1024 to 1035, and almost invariably neutral or alkaline. The children, as a rule, were badly nourished. The doctor believes that the vibriones themselves are not hurtful, but produce a bad change in the milk. Inflammatory globules have been found by Lehman and others, when there was any acute affection in the mother. Vernois and Becquerel found "an excess of butter or caseine always to accompany an ill state of the nursling."—*Walker: The Sanitarian.*

The *German Pharmacopœia* gives an excellent test for the genuineness of raspberry syrup. If one volume of the latter be mixed with half a volume of pure nitric acid (25 per cent.), the fine red color of the syrup must not change to yellow, otherwise the syrup owes its color to some dyestuff which has nothing to do with raspberry fruits. A syrup which contains only a small quantity of artificial coloring-matter remained twenty-four hours unchanged, and only after this time showed a yellow color; while genuine syrup, when treated with nitric acid, even after three days' standing, showed no change of color. It is indispensable that the experimenter should be very careful as to the measurement of the volumes. Dr. Hager states, besides, that syrup colored with aniline becomes colorless when treated in this manner with nitric acid.—*Chemist and Druggist.*

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

EDITORIAL.

PHILADELPHIA HOSPITAL.

A MOST extraordinary discussion occurred a few weeks ago at the meeting of the Social Science Association of this city, which, as it concerns our largest hospital, is of interest to the profession. The occasion was the reading of a paper by a member of the governing board of the Philadelphia Almshouse, in which he demonstrated or asserted the existence, at that institution, of a state of affairs which is simply shocking.

The insane department he described as a vast hostel, in whose wards and corridors the insane are herded together,—the gay and melancholy, the timid and violent, the quiet and noisy,—until from the intermingling of such elements arise a constant noise, excitement, quarrelling, and collision, utterly preventive of recovery or comfort. Moreover, shut up at night by themselves, three in a room six by ten feet, these unfortunate victims of Philadelphia philanthropy are left to prey upon one another, so that, with Dr. Ray, we wonder that "homicide does not occur every night in the year:" in truth, twice within the last few months it has been prevented by the merest accident. Surely we have need of a John Howard among us, if indeed the venerable author of the paper in question be not such a one. We do not propose to devote much space to the consideration of the insane department of the Philadelphia Almshouse. According to the showing of Dr. Isaac Ray, it is but a lazar-house,—a place of confinement, where the city of Philadelphia, too careless, or too penurious, to properly provide for and take medical care of its insane poor, condemns them to perpetual imprisonment. This is the picture that a man who is at once one of the governing board of the institution, and the highest authority in America upon insanity, draws of its corridors. He says, "There can be few more pitiable spectacles than that witnessed there every day, of hundreds of men overcharged with nervous excitement, whose restless movements are confined to the limits of a narrow hall, and of as many more, silent and depressed, crouching down in corners and by-places,—all of them worrying one another, and speedily losing from sheer inaction whatever of mind their disease may have left. To continue this crowding together of the insane, as is still done at Blockley, is simply to perpetrate a great crime against humanity. To ignore the fact and to be reckless of the consequences, is no better, in point of morals, than it would be for a railway company to use a bridge after it had been pronounced defective and dangerous."

The organization of the Philadelphia Almshouse is a simple one. A chief or steward rules absolutely, under the board of guardians, over the whole institution, which is divided into a number of departments, of which the hospital constitutes one, and the insane asylum another. The hospital is under no general government except that of the Hospital Committee and of the steward. The Hospital Committee, composed of men engaged in active business and living miles away from the institution, does all that can be expected of such a body; which, so far as the discipline and daily running of the hospital are concerned, is simply nothing. Auditing accounts, appointing nurses, listening to grievances, and similar general duties, fully occupy the two or three hours of their weekly meeting. The steward has so many duties to attend to in superintending the whole almshouse, that it seems impossible for him to pay especial attention to any one department; and in the past we know that he has very rarely visited the hospital, and has exercised no personal supervision over its daily life.

The astounding fact is but too apparent, that to a hospital of nearly one thousand beds there is no head. Seven or eight nurses, men worth only thirty dollars a month, ruling their wards as best becomes their sense of dignity and right; twelve resident physicians gathered annually from the city and country, and, as a matter of course, some of them men of great ability, some of them men of great stupidity, all of them fresh with the exceeding freshness of

newly-fledged American graduates, generation after generation of them living in open customary violation of the printed rules of the house; nurses and resident physicians *nominally* responsible to twelve visiting physicians who are required to visit the wards only three times a week and are therefore only in truth consultants, *practically* responsible to no one but their own wayward fancies:—such, reader, are the real daily governors of the Philadelphia Hospital. Is it a wonder that one of the guardians of the poor publicly charged and apparently demonstrated that, during the last fever epidemic, men entering the hospital were lost as the wanderer is lost in the vortex of London, no trace remaining, no sign upon the books to tell whether they had died or lived? Is it a wonder that discipline is so loose, if indeed it exist at all?

Who is to blame for this state of affairs? Evidently, no one. Like Topsy, "it has growed." Like some monster, the institution has suffered from arrest of development, while it has continued to expand in bulk. If the responsibility rests anywhere, it is with the Philadelphia medical press, which has failed to raise its voice upon the subject. The evils which have been alluded to are but a fraction of what exist; and we propose, in the next few weeks, to examine closely the Hospital Department, its organization, its executive management, and see how nearly it approximates to the standard that is demanded by modern civilization and charity.

ETHER VERSUS CHLOROFORM.

IN a recent clinical lecture in the *British Medical Journal*, Dr. Jonathan Hutchinson writes decidedly in favor of the use of ether as an anæsthetic in ordinary cases. He, however, claims that in old people chloroform is the safer, and details a case of coma continuing for hours, and finally proving fatal, in a gentleman eighty-four years of age, to whom he had administered ether. As the kidneys were found at the autopsy in an advanced condition of granular degeneration, the question arises, Was not the coma really of uræmic origin? and when it is noted that death did not occur for forty hours after the suspension of the ether, which was only inhaled for twenty minutes, and that there were during this time repeated convulsive paroxysms and twitchings of various muscles, the natural answer to the question seems to us—Yes. It is quite refreshing to see the light of our American science breaking through the prejudices of the English profession; but we think Dr. Hutchinson's preference for chloroform over ether in old persons has no better foundation than had the complete condemnation of the latter anæsthetic so universal in Great Britain a year or so since.

THERE has recently appeared in Paris a curious book,—a veritable encyclopædia of an art most interesting to lovers of hygiene. It is a posthumous Gastronomic Dictionary, by Alexandre Dumas, in which the recipes are piled up from A to Z, and interlarded with amusing anecdotes told in a manner worthy of a Gascon. In it the inquiring mind may find recipes for all things to be cooked, from a swallow's nest to escargots, from beefsteaks to elephants' feet. If it were possible by means of any dictionary to recover upon this continent the lost art of cookery, we should earnestly pray for a translator. What philanthropist will furnish copies to our hospitals?

WE have felt exceedingly honored by the promptness with which our learned cotemporary the *Journal of Materia Medica* copied the article on digitalis in one of our late issues. While, however, we admire the enterprise of the aforesaid journal, an acknowledgment by it of the source from which the article was obtained would have been more in accordance with our taste. *De gustibus non est disputandum.*

WE desire to correct a slight error in our report of the Proceedings of the American Medical Association. The name of the third vice-president elected should read Dr. N. C. Husted, of New York City, instead of W. C. Husted, of Missouri.

CORRESPONDENCE.

May 29, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The leading article, on *Life Insurance*, in the *Philadelphia Medical Times* of May 17, had escaped my attention until the remark was made to me, "That was a good article of yours in last week's *Medical Times*." The article does not strike me as a very good one. It is, certainly, not such an article as I wish to have attributed to me, either for my own credit with a single reader, or for the influence which my supposed opinion may have with any one.

I do not pretend to find fault with the language or spirit of the article; and of course take pleasure in according with all that is said in regard to the importance of having competent and well-paid medical officers, and as to the care with which examinations and inquiries should be made, etc., etc. There is nothing new, or peculiar, or which is not familiar to every good

life-insurance examiner and manager, in all that is said in regard to the independence, honesty, and technical qualifications which are so much needed, in both classes of officers, for the proper conduct of the business. Unfortunately, there is nothing new, either, in the other views expressed, since we read them in the newspapers, meet them more or less in the courts, and hear them too often announced in ordinary conversation. But the prevalence of these one-sided notions, and confusion of ideas, is the reason that induces me, as it might any old life-insurance examiner and adviser, to repudiate and protest against them.

I have neither time nor inclination to discuss the general question, or the many and various particular questions, involved in the study of life-insurance examinations—especially in their business and legal aspects. Nor am I much disposed to dwell upon the provoking muddle in which the writer of your leading article has involved his topic by his inconsequent propositions and assumptions. I must, however, express an absence of faith in his doctrine of unconditional liability. I cannot see how it facilitates a practical approach to what he calls the "selection of the fittest," or affords the slightest tenable reason why swindling in life-insurance contracts ought to be more free and successful than false pretence action in any other bona fide business operation, or how so blind a rule of conduct can do anything but harm to the general interests concerned. I do not believe in his assertion as to the peculiar nature of the bargain which renders this kind of contract unlike all others in the risk which it assumes against the insurer and in behalf of the insured; so that "when once a risk is underwritten the responsibility is assumed, and there is no escape."

The last word is the key, I fear, to the whole paper. Just a whisper of the popular hue and cry! "No escape"—from what? No respectable office wants or tries to "escape" from an ordinary loss. Such losses form a necessary and perfectly natural part of the habitual experience. Every respectable office wants and tries to "escape" from *fraud* in the making of its contracts; and equally wants, but rarely tries, to "escape" from the *consequences of fraud*, in the fulfilment of its contracts. The obligation to resist intentional deception, at all times, is as strong on the part of the company as it is on that of the claimant; but the effort to escape in case of fraud is rarely made by companies, simply because the disposition is always to give the benefit of the doubt, as to the fact of fraud, to the beneficiaries of the policy; and because the effort to escape often fails and too often threatens to cost as much as the policy itself. "Examiner and applicant are alike human," as our friend has it; both have been mistaken, only,—neither deceived or deceiving,—and so the company pockets the loss from the rogues for the sake of peace and good will among honest men; and, especially in mutual offices, at the expense of honest men. The treasury is to be robbed by the successful cheat, not because of his cheating, but because the examiner has failed to prevent him from cheating.

No well-regulated insurance office will admit that "there are but two subjects of inquiry before the payment of a loss,—the *identity* and the *death*." They all know very well that no such absurdity would keep a company together long enough to make many, even of these sometimes difficult subjects of inquiry, possible.* There is quite as much reason for "holding," in a question between a horse-jockey and his victim as to compensation for a horse, that description and guarantee are nothing,—"the only subjects of inquiry" being the identity of the horse and the transfer of the horse. He might be a runaway, hopelessly unsound, or radically vicious. You have bought him on conditions and under certain representations; but, having once "accepted" him, you are bound to pay for him, whether dead or alive, or kicking. The average horse is good and safe and young enough; and you were therefore bound to ascertain, without regard to warrants and descriptions, that he was *not* an average horse before you took him. No one doubts the force of obligation in this lower order of bargaining. Why should there be any less in the higher and more sacred aims and objects of a life-insurance negotiation? The difference is manifestly in the vastly greater importance of care and honesty in attention to the preliminary steps of both parties to the agreement—which is fully recognized by life-insurance companies; and of a strict adherence to terms—which is often waived by the companies in favor of the insured before death, and of the beneficiaries after death.

If the applicants for life-insurance were obliged to register their inherited and other infirmities, diseases, and known liabilities to disease from any cause, as mortgages are registered in the deed-recorder's office, we might, perhaps, substitute searches and briefs of title for written answers to the standing questions; and might, with some greater show of reason, be held—without regard to conditional *history*—as tightly to the consequences as the mortgagor or purchaser of landed property.

But men and women are not so easily surveyed and described, and judged of, as lands, or even houses, or so easily watched, even for the superficial view alone obtainable; nor can their years be told by their teeth so nearly as age is in the horse. Being without these material resources; being, in fact, only mortal in our lack of "perfection and prescience," we naturally fall back upon the practical and inalienable method of dealing with human beings which has governed the world in its business intercourse since the days of Jacob, if not those of Adam. This is what common sense demands, and what our courts require, as the only safeguard for all parties to a bargain.

Life-insurance may be "founded upon absolute certainty, in the death of *all* the assured," but the certainty is in the fact that the "death of all the assured" *cannot possibly occur at any one time*. This difference in

* The West case, in Dover, Delaware, and the Goss case, in Baltimore, Maryland, are the latest illustrations of this difficulty as to identity and death.

time must depend, in the vast majority of cases, upon the varying circumstances of these separate cases. These circumstances, the average influence of which has been long established by indisputable authority, can never be fairly known and judged of without the statements and testimonials of the applicant and his recommenders; and, hence, such stipulated data must be truthful, and so required and agreed to, as the only sure basis of insurance.

It is the well-recognized duty of the medical examiner of the applicant for insurance, and of the medical adviser who has the determination of the risk, to elicit as full and fair an account of the true tendencies and condition, inherited and acquired, of said applicant, as may be practicable; and to advise or object to the acceptance of the risk in accordance with the information thus obtained. They must do this with the clear understanding that nothing but palpable misrepresentation can vitiate that basis of acceptance, and that no forfeiture can follow except through violation of express terms in the policy with which the examiner and adviser have nothing to do. But the necessity for good faith on the part of the applicant under any kind of personal inquiry on the part of the examiner, and in keeping his engagements, is at least as absolute as the obligation to good faith on the part of the company in maintaining the insurance.

The proper physical examination of the applicant is of great importance, certainly,—a *sine qua non*, of course. But can that examination be conclusive without a previous history? Can the history be complete without a family record? Who is to give the history, personal and family, but the applicant and his medical, or other, sponsor, whom he is required to call upon to testify to the previous circumstances—which are necessarily beyond the personal ken of the examiner? And how are these things to be done except through questions and answers, written and oral? The list of printed questions must, of course, seem strangely, absurdly, long and complicated to an inexperienced reader. No well-trained life-insurance examiner need be told that they must be so, in order to include the great variety of cases, incidents, and contingencies; that they are based, not upon theory, but upon long practical experience with the work of investigation, and with its peculiar requirements and difficulties, in the true interests of all rightful parties in the matter.

Shall we then allow so much laborious and painfully minute inquiry after bona fide data—for experience no less than for protection—to be set at naught by a thoughtless prejudice which, whether intentionally or not, could only aid the rogues and mislead the honest men? Must we quietly submit to the assumption that the object and results of all this care must be regarded as little more than pretence and form—surplusage, if not trickery, as to any practical purpose? There is no answer to this view of the argument in the claims of the beneficiaries. Nor is there any in the circumlocution about the waiting for better information and for other proper modes of dealing with the doubtful cases, the selection of officers to "protect the assurers and the assured," and such other truisms and commonplaces, with which your contributor would reconcile his readers to the Utopian idea of absolute security—upon the claimant's side. The greatest care and skill, and the most disinterested and deliberate judgment,—the highest qualifications, in short,—were they obtainable in every case, would have a poor chance, on one side, against dishonesty on the other.

One of the difficulties in collecting information, even for experience purposes, is well illustrated by the writer's remark in regard to a very natural inquiry as to the character of a vaccination in the case of an insured person who had died of smallpox, that it looked "very much like an attempt at quibbling, not at all compatible with the dignity of a great company." So, as to the view that "some" of the questions "which are sent to physicians to answer," in relation to the decease of a policy-holder, "indicate a disposition on the part of the companies to get rid, if possible, of their obligations." This I deny positively as to the company which has been at least twenty-six years under my observation, and I doubt it greatly as to others. The ruling desire is, carefully to avoid the indication of a disposition which there is very little reason to charge them with, notwithstanding newspaper assertions to the contrary. I do not mean to defend the want of courtesy, the rather inquisitorial style, the not very convenient arrangement, and the inexplicit language of these post-mortem interrogatories; such as I have thus far seen at least, savoring, as they do, too much of magisterial dictation; and, while acknowledging no responsibility for these defects, I believe them to be unintentional, and have good reason to hope for improvement in the future.

One thing is very evident in this matter of medical certificates. They should be well paid for when they are good for anything. As they are often very important, however defective, it is probably the best policy to pay well for them, whether good or bad. Being required by the company, they must be procured as legal papers, *by and through* the parties interested in the policies; but it will always be to the interest of a company to bear the expense of a decent fee for such a certificate—as for every kind of medical certificate—not for the purpose of litigation, which is rarely desirable or thought of, or for any merely detective purpose, which is not respectable; but for the vastly more important uses of the experience record.

These questions of life-insurance settlement, however, are not within the jurisdiction of the medical examiner. They are questions of law and equity, to be settled by the courts of justice. But no member of the medical profession should undertake the duty of an adviser in such matters without a clear idea of his whole responsibility as an expert, and of his liability as a witness, in giving his professional estimate of the importance of the scientific data on which the insurers and insured may have agreed to act.

Very respectfully,

EDWARD HARTSHORNE.

PROCEEDINGS OF SOCIETIES.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY.

THURSDAY, JUNE 5, 1873.

SOCIETY convened at a quarter after eight o'clock P.M.

The minutes of the previous meeting were read, and, without remark, stood approved.

Dr. RICHARD THOMAS was then introduced as a new member to the Society.

Two specimens of *hydrops fallopii* were shown by the Secretary, Dr. INGHAM. They were without available history, and in his brief comments he stated that he showed them not so much as rare or uncommon specimens, as to illustrate their dissimilarity. In one, the cyst was entirely free from any signs of surrounding inflammation, while the other was bound down to the walls of the uterus by perimetritic inflammation. The points suggested as presenting interest were: could they have been diagnosed by the introduction of the fingers into the rectum, and, if recognized, whether puncture should have been made for relief.

He also presented a third specimen of a large *fibroid tumor* (size of a large orange) *of the uterus*, seated upon its posterior wall, with two small ones within the walls. No history of the case was offered. The patient died of an intercurrent disease, and without the tumors being recognized.

Dr. JENKS alluded to the great difficulty in diagnosing fibroid and other growths when situated upon the posterior wall of the uterus, even since the discovery by Dr. Simon, of Heidelberg, that the rectum may readily be dilated to admit the whole hand.*

Dr. GOODELL called attention to Hildebrand's treatment of fibroid tumors by hypodermic injections of a solution of ergotine in glycerine. He knew personally of one case in which the tumor was materially reduced in size; another under the care of Dr. Barker, of New York, in which it disappeared entirely; another reported by Dr. Ashhurst diminished one-third in so short a time as three or four weeks. It is not very liable to produce abscesses at the point of injection, though these do sometimes follow. One objection is the intense pain which is produced, amounting in some cases to agony, and requiring drugs for its relief. Dr. Barker also recommends the administration of ergot by enemata and suppositories.

Dr. LUDLOW spoke of a case under his care, where an operation was meditated, but the tumor of late has been diminishing in size, under ergot internally; and of another case of a lady, who was seen by Dr. Hodge, where the tumor disappeared for five years and then returned.

Dr. JENKS stated, for the advantage of those who desired to experiment with the article, that a preparation has been made by Dr. Squibbs especially for hypodermic use, and is reliable.

Dr. GOODELL remarked that, as discoloration is sometimes produced at the point of injection, and is very slow in disappearing, a position should be selected which would not show. Dr. Hildebrand employed a point about the umbilicus.

Dr. LUDLOW objected to this locality, suggesting that peritonitis might result from a deep-seated abscess in this position, and proposed the gluteal region.

Dr. SMITH proposed injecting into the body of the tumor.

Dr. GOODELL stated "that as the theory on which it acts is reducing the nutrition of the tumor through the sympathetic system, no advantage is to be expected from injections into the growth itself."

A unique specimen of *twin embryo* was exhibited, having been forwarded to the Society by Dr. A. S. GERHARD, but without history accompanying.

Dr. SMITH said he had been informed by the doctor that the lady had had several miscarriages previously, and had been regular for months, the last menstrual flow having been very free and lasting several days.

She had passed the time for the next period, five days, when he was called and found an unusually excessive hemorrhage, coming on after some extra exertion on her part, her health having been previously good. On examination he found the cervix hard, rigid, and unyielding, and, after various other methods had failed, the hemorrhage was controlled by the tampon. On removing it, eight hours afterwards, and examining the clot which followed, the "twin embryo" was discovered, surrounded by the decidua, one the size of a hulled walnut, the other half as large again. Owing to the action of the preserving fluid, they are now somewhat smaller. The cause of abortion was, no doubt, dropsy of the amnion, as the sacs are distended to their natural size at the second month, while, from the history of the case, she could not have been more than three or four weeks gone.

Dr. JENKS made some extended remarks upon early ova: for the first five or six days it was supposed to be passing along the fallopian tube (in the bitch accurately ascertained to be ten or twelve days), but in only one case has it been pretended to have been found in the human fallopian tube, and the observations of that case were so imperfectly made that most probably something else was mistaken for it. He considered the observations of Dr. Allan Thompson on the three specimens examined by him at what he supposed to be the tenth, fifteenth, and twenty-first days, with the peculiar changes and developments from one period to the next, desiring that it should be remembered that these were all abortions or pathological specimens, and not the ovum in its natural and normal development. On a hasty examination in the present case, we notice the dorsal plates to be closed, the abdominal plates closed, allantoic membrane formed, eyes formed, ears indicated, upper and lower extremities just budding, as it were. In all probability it is from twenty-five to twenty-eight days old. It is the *first case of twin embryo* reported at so early a period, so far as I am aware.

The report of the committee on Dr. Beecher's case of congenital deficiency of the lower extremities was not read, the chairman of the committee not being present.

Dr. CATHCART exhibited a *carcinoma uteri* which had been treated, with great relief for a time, by scraping. Afterwards the cervix was removed at the suggestion of Dr. PARRY, who remarked to the Society that "the case was peculiar, insomuch as it had involved to so great a degree the body of the uterus, and as connected with a statement made by a German writer some two years ago, that uræmia resulting from hydronephrosis was the frequent cause of death in cancer of the uterus. Here we had a dilated ureter, with absorption of a portion of the kidney, but on close examination it was found that the obstruction was not due to extension of cancer, but to surrounding pelvic peritonitis."

* As some of our readers may not have seen the paper of Dr. Simon in the *American Journal of Obstetrics*, February, 1873, it may be well to state that he claims that the whole hand may be so introduced into the large intestine that physical explorations may be made of the lower two-thirds of the abdomen. A person with a hand having a circumference of over ten inches cannot do this; but when the hand is small, by folding it into a cone and oiling it, it can be readily introduced, the patient being in a state of anæsthesia.—ED. *M. T.*

DEATH FROM THE ANTISEPTIC USE OF CARBOLIC ACID (*British Medical Journal*, March 1, 1873).—David I. Hamilton details a case of death occurring in a child four and a half years old, from absorption of carbolic acid by a wound four inches long.

GLEANINGS FROM OUR EXCHANGES.

On Canine Madness.—In a paper on the above subject (*British Medical Journal*, March 8), Dr. E. P. Philpots writes as follows concerning the diagnosis of true and false madness in dogs:

HYDROPHOBIA.	DISTEMPER-MADNESS.
Definition.—A fatal form of madness communicable from the lower animals to man; characterized (as the name denotes) by an intense dread of water.	*Definition.*—A form of rabid madness non-communicable to man; characterized by foaming at the mouth, impairment of deglutition, and a desire to vomit.
Synonyms.—None.	*Synonyms.*—Rabies.
Premonitory Symptoms.—Begin two days beforehand, loss of spirits, loss of appetite, general depression.	*Premonitory Symptoms.*—Loss of appetite, and slight husking in the throat.
General Appearance during the Attack.—When let alone, the dog lies sullenly as if "out of sorts" and depressed, notices little, but recognizes his master by wagging his tail. Violently insane only on the approximation of water.	*General Appearance during the Attack.*—The dog bites at any of its fellows, gnaws at his bed, or the wall, eats straw, snaps at his attendant.
Fits.—Absent.	*Fits.*—Present in a marked degree, in most cases.
Foam at the Lips.—Absent.	*Foam at the Lips.*—Very much; the dog leaves it on the surface of the water he vainly tries to drink (the foam is caused by futile efforts to drink or swallow).
Water.—Sprinkled over or near him, causes violent convulsions.	*Water.*—Has no effect upon him.
Thirst.—Absent.	*Thirst.*—Intense, insatiable.
Desire for Water.—Absent on account of dread.	*Desire for Water.*—Very great.
Appearance of Eyes.—Dull or heavy.	*Appearance of Eyes.*—Dull, and green in their reflection.
Howling and Barking.—Absent.	*Howling and Barking.*—Present.
Muscular Affection of the Throat causing Inability to Swallow anything.—Absent, or not observable.	*Muscular Affection of the Throat causing Inability to Swallow anything.*—Well marked.
Causes.—None.	*Causes.*—Inflammatory action internally pervading the system.
Prognosis.—Very bad, always fatal, no chance of recovery.	*Prognosis.*—Good, or bad, according to the severity of the fits.
Terminations.—The symptoms do not vary to any great extent towards the termination.	*Terminations.*—A fit.
Pathology.—Intense inflammation of the brain extending to the throat and lungs.	*Pathology.*—Inflammation of the brain, often extending to the throat, the lungs, and the intestines.
Prophylactic Treatment.—None.	*Prophylactic Treatment.*—Vaccination is a certain preventive.

It will be noticed by this table that in hydrophobia there is a dread of water, and in distemper-madness there is a longing for it. In the latter disease, there is a spasm of the œsophagus which the dog tries to overcome by futile efforts to vomit.

The premonitory symptom of hydrophobia is a sullen depression; in distemper-madness the throat-symptoms are first observable. Regarding the general appearance during the attack; the hydrophobic dog is a sullen animal, merely appears much "out of humor," and is only actually mad on the approach of water; but in distemper-madness the animal really *is* mad in every sense of the term. He bites, and gnaws, and snaps, and chews anything that he thinks will cause him to vomit. The hydrophobic dog has *no* fits (except on the approach of water), and he does not foam at the mouth; but with the dog mad with distemper there is a succession of fits, one of which may end his life; his saliva, some of it of a frothy nature (foam), dribbles, and exudes from his mouth, and water sprinkled over him has no effect upon him. The hydrophobic dog hates the sound, the sight, the thought, of water, and will fly from it madly; but the dog mad of distemper rushes to it to assuage his thirst, but this he cannot do, as spasm of the œsophagus will not allow his swallowing. The hydrophobic dog's eyes are "fishy," dull, and sullen-looking; the dog ill of distemper-madness has bright, green, and savage-looking eyes, and he howls and barks. Dogs never recover from hydrophobia, but they do from distemper-madness, if the fits be not severe. Vaccination does not prevent hydrophobia, but it does distemper-madness.

Lactic Acid in Diabetes.—In the *British Medical Journal* of March 8, Dr. I. W. Ogle reports two cases of saccharine diabetes treated with lactic acid, and remarks upon them as follows:

In Case No. 1, which was under care for seven weeks, no marked diminution of urine, and no change in the specific gravity, were noticed; but after the long use of the lactic acid, and possibly in consequence of it, great constipation came on, requiring active aperients. The weight fell from 8st. 5lbs. to 7st. 7lbs. The temperature was chiefly *above the normal;* on one occasion only being below, and then it was 97.4 deg. Fahr.; on one occasion it reached 102.8 deg. Fahr. No pain and no excess of perspiration existed during treatment.

In Case No. 2, which was under treatment for eleven weeks before the lactic acid was given, the urine ranged in quantity between 112 and 178 ounces a day; after the use of the acid the quantity quickly diminished, and throughout its use fluctuated between 40 and 70 ounces a day, on one occasion being as low as 30 ounces. During all this period the specific gravity remained much the same as when the patient came to the hospital. The weight fell from 7st. 3lbs. to 6st. 8lbs. The temperature was almost always *below the normal,* being for the most part below 98 deg. Fahr. Neither the morning nor the evening temperature was uniformly above or below the other.

In neither Case 1 or 2 was there any indication of interference with, or affection of, the nervous system; power of movement of the entire muscular system, and sensibility, both general and of particular organs, being unaffected. In neither case was there albumen or excess of uric in the urine, nor did rheumatic pains or excess of perspiration ensue; and in neither was there any decided lung-mischief, though in Case 2 there was a degree of harshness of respiration.

As regards the results of treatment, it did not appear that in these cases any real benefit arose from the administration of the lactic acid.

Death during Etherization.—In the *Boston Medical and Surgical Journal* of May 29, Dr. Cabot reports the following:

"An old man, weak, but not excessively so, had undergone an operation which lasted three-quarters of an hour. He was removed from the operating-room, and the usual orders to watch him were given. Five hours afterwards he had a violent attack of dyspnœa, and died. Food was found in one of the bronchial tubes.

"He also referred to a similar case which had occurred some time ago. A fat woman, while lying on her back under ether, vomited, and some of the vomit getting into the trachea killed her."

MISCELLANY.

The Milk of Human Kindness.—The history of the great saving of life now effected in the transport of government convicts and of emigrants is so striking and so simple that it cannot be too often recalled to mind. At the commencement of the transport service of convicts, and, indeed, of emigrant passengers, the loss of life was terrible: an epidemic broke out, and a third, and, in one instance, nearly half, were thrown overboard before arrival. And yet there was nobody to punish. The skippers did not intend to kill the passengers, but

they wanted room for cargo, they did not think of the results, and so there was overcrowding,—sanitary science and ventilation being then unknown. At last some unknown civil servant got an alteration made—only one—in the terms of the contract, from payment per head on the number embarked, to payment per head on the number landed alive. Under this condition the whole state of things was changed. The skippers of their own motion got medical officers, and paid them for results. Sanitary science gleamed on these voyages. The skippers listened eagerly, and adopted zealously any suggestions made for improvement. They were their own inspectors, and they wanted no regulations. The work of benevolence was done without benevolence. For every poor lone passenger who happened to die during the voyage, one sincere mourner at the least was secured!—*British Medical Journal.*

A Remarkable County.—The Medical Society of the State of New York has recently made it obligatory on the part of every county society to examine all gentlemen intending to study medicine, and give them a certificate of their fitness. How far this provision is carried out we are not able to say. We know of two *counties* in the State who (*sic*) make it a regular practice, one of which is the *Ulster County Medical Society* (!). We were present at the last monthly meeting of this body, and witnessed such an examination, which was remarkably thorough, and conducted by the committee with a determination to fulfil the full letter of the law.—*New York Medical Record.*

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 3, 1873, TO JUNE 9, 1873, INCLUSIVE.

Smith, A. K., Surgeon.—Assigned to duty as Chief Medical Officer, District of New Mexico. S. O. 84, Department of the Missouri, June 4, 1873.

Alexander, C. T., Surgeon.—Relieved from duty in Department of the Missouri, to proceed to St. Louis, Missouri, and, on arrival, report by letter to the Surgeon-General. S. O. 113, A. G. O., June 5, 1873.

Gray, C. C., Surgeon.—Assigned to duty as Post Surgeon at Fort Clark, Texas. S. O. 96, Department of Texas, May 26, 1873.

Town, F. L., Surgeon.—Granted leave of absence for thirty days, with condition to make satisfactory arrangement for medical attendance during his absence. S. O. 104, Department of the East, June 5, 1873.

Fryer, B. E., Surgeon.—Assigned to duty at Fort Wood, New York Harbor. S O. 106, Department of the East, June 7, 1873.

Greenleaf, Charles R., Assistant-Surgeon.—When relieved by Assistant-Surgeon Huntington, to comply with orders received from War Department. S. O. 60, Department of the Columbia, May 23, 1873.

Huntington, D. L., Assistant-Surgeon.—Assigned to duty as Post Surgeon at Fort Lapevoi, Idaho Territory. S. O. 60, c. s., Department of the Columbia.

Brewer, John W., Assistant-Surgeon —Assigned to temporary duty at Fort McHenry, Maryland. S. O. 106, c. s., Department of the East.

Miller, G. McC., Assistant-Surgeon.—Relieved from duty in Department of the South, and ordered to Department of Arizona. S. O. 113, c. s., A. G. O.

Koerper, E. A., Assistant-Surgeon —Granted leave of absence for thirty days. S. O. 112, A. G. O., June 4, 1873.

Yeomans, A. A., Assistant-Surgeon.—When relieved by Assistant-Surgeon Matthews, to comply with orders received from War Department. S. O. 106, c. s , Department of the East.

Patzki, J. H., Assistant-Surgeon.—Granted leave of absence for four months, with permission to go beyond sea. S. O. 115, A. G. O., June 7, 1873.

Matthews, W., Assistant-Surgeon.—Assigned to duty at Fort Sullivan, Maine. S. O. 106, c. s., Department of the East.

King, William H., Assistant-Surgeon.—Relieved from duty in Department of the Missouri, and ordered to report to the Commanding General, Department of the South, for assignment. S. O. 113, c. s., A. G. O.

Byrne, C. B., Assistant-Surgeon.—Relieved from duty in Department of the Columbia, to proceed to Baltimore, Maryland, and, on arrival, report by letter to the Surgeon-General. S. O. 113, c. s., A. G. O.

Weekly Return of Deaths and Interments in Philadelphia for the Week ending Saturday, June 7, 1873.

ORIGINAL LECTURES.

CLINICAL REMARKS ON THE DIAGNOSIS OF APOPLEXY.

BY DR. H. C. WOOD, JR.,

Lecturer on Diseases of the Nervous System in the University of Pennsylvania.

GENTLEMEN:—Among the *οἱ πολλοι* the diagnosis of apoplexy is considered a very simple matter, but, in reality, to determine whether a patient is or is not suffering from cerebral hemorrhage is often a difficult, nay, an impossible, task. As an instance of an ordinary case of apoplexy, the following is related:

R. P., aged 65, on September 5, 1871, an hour or so after a heavy dinner, heard of his having received a government appointment for which he had been very anxious. At 6½ P.M. he took a cup of tea at a friend's, after which he returned to his lodgings; and at 7.30 P.M. persons passing by on the opposite side of the way were startled by a man at the window calling "Murder! help!" The persons in the house had previously heard pounding in the room, but thought nothing of it, as Mr. P. had been in the habit of stamping documents or letters there. On going up-stairs, Mr. P. was found lying on the floor in a semi-unconscious state, but, on being aroused, he stated that some one had hit him violently on the right side of the head. Dr. Adler, being called, found him, at 7.45, perfectly unconscious, with right pupil dilated; left contracted; the right leg in a state of exceedingly rapid vibration; convulsions; stertor; face not drawn; skin pale and cool. These symptoms persisted, except the convulsions, which soon passed off, and the man died about 11.30.

Autopsy.—Kidneys decidedly granular; brain, an enormous clot breaking down all of the centre of the right posterior lobe, and also the septum between the two hemispheres; it evidently first started in posterior cornu of the right ventricle.

In this, as in most other cases of cerebral hemorrhage, the prominent symptoms were disturbance of consciousness and unilateral disturbance of motility. Neither of these symptoms is, however, constantly apparent.

Thus, in apoplexy, a small clot may affect motility without causing loss of consciousness, or the whole body may be so relaxed and quiet that no difference can be perceived in the two sides.

When to these facts is added the circumstance that loss of consciousness may occur, and even be accompanied by unilateral paralysis, without cerebral hemorrhage, it is very apparent that the diagnosis of the latter lesion is often attended with great difficulty.

My own experience has been that this difficulty is even greater than the facts above narrated would indicate; for I have seen large cerebral hemorrhage occur without either immediate loss of consciousness or disturbance of motility. The following case is offered as proof of this assertion:

William Wilson, aged 70, came into the wards of the Philadelphia Hospital, October 14, 1872. The day after he came in, he seemed sleepy and stupid, but gave a perfectly rational account of himself, complaining only of pain in his stomach, and of vomiting after eating. There was a distinct systolic apex-murmur, and there were also sonorous râles in both lungs. He went about the wards freely, and nothing was discovered pointing towards the existence of nervous disease until November 1, when I noticed a decided paresis of the left leg, which, according to the testimony of the nurse, had gradually developed during the previous week, at first showing itself by a faint limp or halt in his gait. In the arm there were only the slightest traces of defective nerve-power; in the face none. The pupils were normal; the intellect was evidently affected, dulness and drowsiness having come on during the last few days. His symptoms now rapidly increased. There was no headache, but the drowsiness deepened into stupor, the paresis into paralysis, which by the 6th of November affected the face, and on November 9 he died, after having been comatose for some time.

The following is a record of his temperature as taken simultaneously in the two axillæ:

Nov.	3,	12	M.,	Right axilla	102°	Left axilla	102°

"	8,	6	A.M.,	"	99°	"	100°
"	"	4	P.M.,	"	103½°	"	104°

Autopsy, November 10.—Occupying the extreme anterior cornu of the right cerebral hemisphere was a clot the size of a walnut, certainly of some considerable age; yellowish in the centre. The whole right anterior lobe was involved in secondary softening.

Such a case as this, gentlemen, is an exceedingly rare one. In all probability, the rupture of the blood-vessel which caused the hemorrhage occurred some time during sleep; else there would have been some moment of unconsciousness, or some instantaneous sense of shock in the brain. Granting that the clot was formed during sleep, the case becomes parallel with one described by Abercrombie, in which a lady fifty-six years of age, and enjoying good health, was suddenly seized with violent pain in the head, and giddiness, and soon after lost her consciousness for a moment or two. No paralytic symptoms occurred for two weeks, when she had a distinct second attack of apoplexy, and died.

I think these facts are enough to convince you, without further illustration, of the difficulty that may attend the diagnosis of cerebral hemorrhage. The affections with which it is most likely to be confounded are, cerebral thrombosis, simple apoplexy, poisoning from alcohol or opium, and uræmia.

The following case will show you that thrombosis may put on the exact features of apoplexy. I do not think that the diagnosis is of practical importance; for in a case of thrombosis but one end can occur, and, whether you bleed or stimulate, the result will only be that for which the doctor is never blamed in apoplexy,—namely, death.

Jane F., colored, 65 years old, was suddenly seized on August 13, 1872, with a convulsion, whilst in the ward of the Philadelphia Hospital. She remained unconscious for about fifteen minutes, and when she awoke had marked left-sided hemiplegia, in which the face participated. The next day she could only move the fingers and toes very slightly; her mental condition was very dull, and she had an aphasia which was apparently ataxic.

On the 19th of August she died. At the autopsy a firm white clot was found in the right middle cerebral artery, with softening of the anterior lobe.

The term simple apoplexy is applied to those rare cases in which death occurs with all the symptoms of cerebral hemorrhage, and yet on post-mortem examination no lesion is found. To distinguish these cases during life from true apoplexy is simply impossible, and I do not propose to enter at all upon their discussion to-day.

The important practical difficulties in apoplexy arise in regard, especially, to poisoning and to uræmia.

The two poisonings which, from their resemblance to apoplexy and from their frequent occurrence, are most apt to be confounded with it, are those induced by alcohol and by opium.

It may be laid down as a practical aphorism that there is no symptom which will justify a physician, when called to a man who has been found insensible, in pronouncing positively that the case is one of drunkenness. Mistakes have very frequently been made, and men have been left to "sleep it out," who have slept on into the sleep that knows no waking. Further, apoplexy may come on during a condition of drunkenness, and its onset be unnoted until death unexpectedly results or the patient wakes up hemiplegic.

Thus, Dr. Hughlings Jackson mentions a case in which the alcohol impregnated not only the breath, but the urine also, and in which the patient was left to sleep it off. After death a clot was found covering nearly the whole of one hemisphere.

The following case also illustrates this point:

Bridget K., æt. 20, intemperate, came into the wards of the Philadelphia Hospital, April 13, 1872, suffering from paralysis of right face, arm, and leg. The paralysis was complete in arm and leg, with great relaxation and no contraction of muscles; that of the right side of the face, however, though very marked, was not absolute; the forehead was smooth, but there was no interference with closure of eye. Articulation was very imperfect.

For four or five days after admission, on being asked any question, the patient would assume a troubled expression as if of "trying to think," and would invariably preface her answer with, "You may say—" Her statements, at intervals of a few minutes, were discrepant. If taxed with telling an untruth, she would laugh, and seemed to delight in puzzling or misleading her interrogator.

Her mother says that the patient had been indulging very freely in liquor; that she was put to bed drunk on the night of April 8, and the next morning on awakening was paralyzed as at present.

This woman remained in the hospital until July 18, 1872, when she left the wards. At that time the leg had so improved that she could walk by means of a cane, but the arm was powerless, and the flexors of the fore-arm were very much contracted. After leaving the institution she resumed her habits of drinking, and late in October returned to the wards. Directly after this she died suddenly of œdema of the lung.

At the autopsy the remains of a clot were found in the left corpus striatum. The kidneys were granular.

When a patient is first seen during the advanced stage of opium-poisoning, the resemblance to apoplexy may be just as close and the diagnosis just as uncertain as in alcoholic poisoning. The following case will serve to illustrate this, as it was one in which the diagnosis of opium-poisoning was during life considered as warranted by the facts of the case, but was abandoned after death on account of the lesions found, although, as seems to me at present, the case was very probably one of such character. Before stating my reasons for coming to the latter conclusion, let me relate the circumstances.

Bridget ——; æt. 47; Irish; entered the Philadelphia Hospital with acute rheumatism. Late in the evening of November 29 she received, according to orders, thirty drops of the deodorized tincture of opium. On the morning of the 30th Dr. Potter was called, and found her unconscious, with stertorous breathing and contracted pupils. The pulse could just be counted. I saw her first at 8.25 A.M. She could then be roused sufficiently to say a word or two, but immediately relapsed into deep unconsciousness. Respiration 18 per minute. The pulse was so feeble that it could not be counted, but was beating over 150 a minute, and barely perceptible. Ordered f℥ij whisky, atropiæ sulph. gr. $\frac{1}{64}$ hypodermically. The battery was also brought into requisition.

9 A.M.—No improvement.

9.10.—Placed her in a bath at 117° Fahr., and applied the cold douche to her head and chest.

9.15.—Respiration deeper. Pupils slightly relaxed. Atropiæ sulph. $\frac{1}{60}$ grain injected.

9.25.—Pulse somewhat stronger.

9.40.—Put her in a bath at 120° Fahr. for 1½ minutes, using the cold douche as before.

9.45.—Pulse unchanged. Pupils dilated to nearly natural size.

10.—Skin moist; breathing somewhat easier. Pupils well dilated.

10.50.—The heart's action is evidently growing weaker. Its beat, as counted on auscultation, 140. After this about half a drachm of strong liquor ammoniæ was injected into a vein in the arm, without any apparent effect, and she died of failure of the heart's action at 2.30 P.M.

At the autopsy nothing abnormal was found, excepting a firm white thrombus occupying the anterior and middle cerebral arteries on each side, and extending a short distance into the carotids. The anterior lobes were, of course, very anæmic. The heart contained firm fibrinous coagula.

In deciding as to the cause of death in this case, it is evident that the first point to be determined is whether the thrombi in the cerebral arteries were the cause of the attack, or whether they were developed during the long, intense depression of the circulation which preceded death. Let me call your attention, then, to the fact that they were not embolic in nature, as there was no diseased valve or similar depot to furnish the material to plug up the arteries. What should cause a thrombus to form in a young, healthy woman? On the very

face of it, the idea that those thrombi were spontaneous, occurring before the failure of circulation, is an improbable one. Further notice that both sides are symmetrically affected; that in each the anterior and middle cerebral and even the carotid arteries are affected. It is simply inconceivable that a thrombus should form in such manner in a woman of the patient's age, or indeed of any age, whilst the circulation was at all active. I think it may be laid down as a law that thrombi forming in a cerebral vessel are due to a disease of the coats of that vessel. There is no marked disease of the walls of this woman's arteries. The symmetrical character of the coagula, and their extensiveness, show that they are due not to local but to general causes. Look at the heart: its cavities are filled with coagula as white, as fibrinous, as those in the vessels. Would any one maintain that the heart-clot was not formed during the long hours of almost suspended cardiac action that preceded death? Evidently the cerebral thrombi were of the same nature as the cardiac, their origin during the same period, and from the same causes. In regard to the amount of laudanum administered, the statements of the nurse must be taken *cum grano salis*. She may speak the truth; she may have made a mistake without knowing it herself; she may be purposely concealing her handiwork. Who can tell? The case seems to me to have been one of opium-poisoning, because the symptoms are in accord with such view, whilst at the post-mortem nothing to account for the fatal result was, in my opinion, discovered. Notice, I pray you, however, that I say *seems*, for the diagnosis is by no means a certain one: there is no absolute proof that the woman died of poisoning.

The facts being as they are, the diagnosis of apoplexy being in some instances at once so difficult and so important, it behooves us to consider closely what are the points to be looked at when called to such a case. As the patient lies before you unconscious, you should first test the extent and amount of that unconsciousness by shouting in his ear, shaking him, etc., and should note whether he can or cannot be roused out of it. Then the existence of local paralysis should be looked for. If it be found, it demonstrates that the case is not one of poisoning. Remember, however, on the other hand, that your inability to find the local paralysis by no means proves the absence of a cerebral clot.

There are two sets of apoplectic cases in which you may not be able to perceive any difference in the two sides,—the one where, as in the case narrated earlier in my lecture, there is an enormous clot oppressing the whole brain; the other where the clot is small but lies near the centre of the pons varolii, and consequently affects both sides of the body equally. It is plain that in the first case you will have the most profound unconsciousness; in the latter the unconsciousness may be much less marked, so that the patient can be aroused. Unless in the very last stages of opium and alcoholic poisoning, the patient can by loud shouting and severe shaking be aroused; so that you can distinguish the apoplexy of the profounder type with a certain amount of probability by the mere absence of capability of being aroused. Moreover, an examination of the pupils in this form of apoplexy will often reveal a decided inequality. As such inequality is hardly conceivable in poisoning, its importance is at once manifest. If there be a history of sudden attack, an unconsciousness complete, an inequality of pupils, the attack is almost certainly apoplexy, of some form,—probably due to a large cerebral hemorrhage. In hemorrhage into the pons, convulsions are almost invariably present; and, as their occurrence is very rare in poisoning from alcohol or opium, they are of diagnostic significance.

By attending to these points you will almost always be able to make a probable diagnosis. But, gentlemen, do not be too positive or outspoken in your assertions to the friends of the sufferer. Especially is it incumbent on you to hold your peace if you suspect poisoning.

In regard to the development of apoplexy during drunkenness, you should be led to suspect it when there is a sudden deepening of the unconsciousness into complete coma and a sudden development of stertorous breathing, especially if this change of symptoms occur after a fall or a blow upon the head. Remember, however, that unless in very marked cases the diagnosis is rather a matter of suspicion than of scientific deduction.

In regard to uræmia, in most cases the confounding of it with apoplexy is inexcusable; and yet it is sometimes unavoidable. I have seen one case in which I made the diagnosis of cerebral hemorrhage on account of the sudden development of unconsciousness with a perfectly marked hemiplegia, but in which an autopsy showed that there was no brain-lesion,—simply advanced contracted kidneys. You may call the case simple apoplexy, but I cannot help believing that the origin of the symptoms was the same as that of the more ordinary manifestations of uræmia.

Generally in uræmia the gradual onset of the drowsiness, the state of semi-coma out of which the patient can be momentarily aroused, the absence of paralysis, and the presence of convulsions, make the diagnosis easy enough.

ORIGINAL COMMUNICATIONS.

GLEANINGS FROM HOSPITAL PRACTICE—GUNSHOT WOUNDS OF THE HEAD.

BY H. E. WOODBURY, M.D.

DURING my service as a member of the medical staff of Armory Square General Hospital in 1864 and 1865, I met with many novel and interesting cases of gunshot wounds. It has been my purpose to publish a brief history of some of these, but other demands upon my time have prevented me from so doing. As our hospital was located only a few blocks from the steamboat wharf, we received a majority of the worst cases.

Case I.—In 1864, Major H., of a New York regi-

ment, was brought into my ward wounded. A bullet from a carbine or navy revolver struck the dorsum of the nose at a point about one inch below its summit and passed into the head and brain. I did not deem it expedient to probe this wound to any great extent, but satisfied myself, by passing a silver sound for about two inches into the opening (which was very small), that no spiculæ were present. At least I could detect none. I applied a cold-water dressing, ordered "special diet," and pursued the expectant plan. After a few days there was a somewhat offensive discharge from the nostrils, for which antiseptic injections were used. The patient was a man of great determination and of strong constitution. In a few weeks his wound healed, and he desired to walk about the ward. On making the attempt, he found that he could not stand without assistance, and, even when supported, he had lost the power of locomotion to such an extent that he could not take one step. This was the interesting phase in his case.

I at once ordered strychnia with dilute phosphoric acid, and directed him to renew his attempts to walk daily. In about one week he had so far recovered the use of his limbs that, by taking hold of the wire by which the musquito-nets were suspended, he could shuffle himself across the ward. From this time he continued to improve, until at length he had gone through the process of learning to walk, if so I may express it.

He left for his home, on furlough, after having been a patient about two months, and on his return, sixty days after, he had gained so much that I did not recognize him. "Doctor, you do not remember me," he said, pointing to a very small scar on his nose,—when I at once called him by name. He then informed me that his wound had caused him no trouble during his absence, that his health had never been better, and that he was on his way to duty, "to take another chance at them." I have never seen him since.

In this case, I have no doubt, the ball penetrated and was lodged in the cerebellum, causing, by the irritation it produced, temporary paralysis of that portion of the brain. During the entire course of treatment there were no other indications of cerebral derangement,—no delirium—and very little, if any, febrile excitement.

Case II.—Private B., admitted from the army of the Potomac, in September, 1864. A fragment of shell struck him on the forehead, cutting away a portion of the cranium (frontal bone), and leaving the brain exposed and lacerated. The wound was nearly oval in shape, and included the upper third of the forehead, extending backward nearly to the coronal suture. When brought in, he was in a comatose condition, from which he never rallied. Cold-water dressings were applied, and frequently changed. On the third or fourth day after admission, while the dresser was changing the lint, a fearful hemorrhage ensued. He at once called me, and I took up the meningeal artery and ligated it. I reported the fact to the surgeon in charge. "It will do no good, doctor," he replied, "for sloughing will take place, and your man will die from hemorrhage." His prediction was not verified, as the patient lived forty-eight hours, and then died without having lost another drop of blood,—probably from nervous exhaustion.

Case III.—Private G., admitted November, 1864, from the army of the Potomac, with gunshot wound of the head. A minie-ball struck the frontal bone at a point about one and a half inches in front of the coronal suture, and an inch to the left of the median line, cutting a neat furrow from two to three inches in length, and leaving the brain exposed. Cold-water dressings were ordered, with light nourishing diet, and perfect quiet. In a few days profuse fungous granulations made their appearance in the wound. These I clipped off with the scissors, and touched the parts from which they sprang with nitrate of silver. A healthy action speedily followed, and after a sojourn of six weeks in the hospital the patient left, apparently as well as ever, for a visit to his home.

My experience and observation in the service convince me that, as a general rule, the probing of gunshot wounds of the head is inadmissible. In short, in all cases of gunshot wounds, the less we use the probe the better. In 1863 I saw in Seminary Hospital, Georgetown, a German who had received a ball (probably a round one from a smooth-bore) in the temporal region just in front of the ear. Two medical officers were present with me at the time. We each in turn examined the wound with the little finger. This was passed in its entire length. No probe or sound was used. The water dressings were applied, and in thirty days, to our surprise, the man was fit for duty. I have no doubt a moderate amount of probing would have produced a very different result in this case.

WASHINGTON, D.C., June 9, 1873.

THE DOSE OF CARBOLIC ACID.

BY DR. W. G. COTTON,

East Bethlehem, Washington Co., Pa.

THE following case is of interest, as showing that we may yet be unacquainted with what should be the proper dose of carbolic acid in some instances. Mrs. Moffitt, aged 70, was suffering from diarrhœa, for the relief of which she requested her husband to pour out twenty-four drops of laudanum. He by mistake gave her that amount of crude carbolic acid. It "burnt" the mucous membrane of the mouth and throat considerably, and produced a moderate amount of nervous prostration, which did not last long. She at once was aware there had been a mistake made, but thought the drug taken was "pain-killer." In about an hour afterwards the discovery was made that carbolic acid had been taken, and milk was then freely used as an antidote. The evil which resulted was immediate, but immaterial, and the good accomplished was the relief of the diarrhœa. I would not recommend twenty-four drops as a proper dose of this fluid, but have an idea that one drop is rather homœopathic.

TRANSLATIONS.

HYPNOTISM OR BRAIDISM IN ANIMALS.

An abstract of two Lectures delivered by Prof. Joh. Czermak in the private Physiological Laboratory of the University of Leipsic and published in *Die Gartenlaube*, Hefte 2–3, 1873.

BY DR. WILLIAM ASHBRIDGE.

THE subject of the two lectures of which this article is an abstract is one that is of interest in two respects. The physiological appearances of which descriptions are given, and which are demonstrated upon animals of various sorts, considered by themselves are in the highest degree surprising and wonderful; and, on the other hand, they show how readily men, even when of fair education and good abilities, fall into error in the deductions which they draw from their observation of natural phenomena, if they are lacking in that special scientific training which alone can render them capable.

The want of discrimination and the prejudice of such observers are astonishing, and prove how little weight the scientific investigator dares give their statements. The witness certainly was present and heard and saw all that occurred, yet still what he asserts must not be accepted as accurate, although no doubts of his veracity are entertained. This apparent paradox is explained by the fact that such observers cannot judge between mere co-existence or sequence in time and the relation of cause and effect: they make the frequently-committed error of substituting "propter" for "post hoc," and thus draw a worthless inference.

The best designation for occurrences of this character is that of "insufficiently proven," or "inaccurately observed;" and the establishment of this category of natural phenomena, so far from being only allowable, becomes almost obligatory, for it deals with a class of subjects which play an important *rôle* in the intellectual development of man. The inaccuracy of the unscientific in these matters deserves this notice; for it is only by careful and accurate observation that the spread of credulity and superstition can be prevented.

We children of the nineteenth century are not a little proud of our civilization, cultivation, and enlightenment, and indeed, in comparison with the Middle Ages, justly so; for since then mighty steps in advance have been made; but, at the same time, our self-approbation should not be too great; for even at present we find theories and beliefs prevalent which would not be listened to a moment if the mass of the people had the vaguest idea of the true methods or results of the study of nature, or a little more respect for them as taught by those worthy of credence.

To give a catalogue of these things would be tedious: it will suffice merely to name the usual manifestations of the spiritualist, table-turnings, spiritual rappings, etc., and animal magnetism, so called. What has been said has been but by way of introduction to our proper subject, those wonderful physiological appearances in animals, which, although long known, have been but recently made the subject of scientific research, under the name of Hypnotism or Braidism, and scarcely yet admitted into the regular list of the phenomena of the physiology of the nervous system.

The attention of Prof. Czermak was called to this subject by the assertion made by a casual acquaintance that he had frequently seen crabs "magnetized," and had even succeeded in doing it himself. This was accomplished by holding the crab with one hand and with the other making "magnetic passes" from the tail to the head of the animal, which under this manipulation soon ceases its struggles, and allows itself to be placed upright, standing upon its claws and head. The crab remains in this state till, by "passes" in the reverse direction, it is "unmagnetized," when motion reappears, its equipoise is lost, and its full activity returns.

If the same experiment is made, omitting the passes, *i.e.*, if the crab is placed upon its head and two claws and held in that position, after a time the same phenomena will be seen: the animal ceases its struggles and becomes motionless in the unnatural position which it has been forced to assume. To have the return of activity we have but to wait, and, omitting the magical passes altogether, the animal in a short time resumes its wonted movements. The utmost influence that can be laid to the "unmagnetizing" process is that it may by currents of air or the increase of temperature accelerate the return of functional activity to the nervous system. The truth of the matter is, the passes are made and the loss of motion follows, but the relation is but one of time, not of cause and effect. The same results are obtained by suspending the animal by its tail by means of a thread, or even by holding it upon its back by means of a glass rod: in both cases there occur vain struggles followed by immobility. In these last two experiments there can be no question of magnetic force going forth from the experimenter, and yet the same ends are attained. Still further, a careful observation of these animals shows that at certain seasons they fall into this state without any outward influence whatever, so far as can be seen. The so-called magnetizing them by accurate testing and observation shows merely that these animals possess the wonderful power of losing the irritability and conducting power of their nervous system for a time if held in a certain position, in spite of the resistance made by them at first; the passes have nothing whatever to do with the result.

The well-known experiments with hens made as early as 1646 by a Jesuit, by tying the feet, drawing a line from the beak with chalk, and then removing the band from the feet, the hen remaining perfectly quiet for a variable length of time, can be done just as well with the omission of the chalk and the confining band: simply holding the bird in the unnatural position with the neck stretched out, will suffice. Ducks, geese, and even swans, can be treated in a similar way with similar results. In some of the smaller birds the hypnotic state can be induced by holding them on the back, fixing the head by the thumb and finger, and stretching the head and neck somewhat backward: the bird lies still, breathing strongly, but in other respects as if sleeping, in this unnatural position.

A frog laid upon its back quickly seeks to regain its natural position; but by tying a band moderately tight around the upper part of each leg and then placing the animal on its back, it is thrown into the same state as the other animals upon which the experiments have been made. When the pressure made upon the nerves of the skin by the cords is removed, the effect remains some little time, but gradually the frog regains its wonted activity. That in this case the effect depends upon the impression made upon the nerves of sensation, can be demonstrated by the section of these trunks, when these results no longer follow the application of the cords to the limbs. After this experience with the frog, it would appear that the tying of the legs of chickens in the old experiment, although not essential, is still of some influence, and that the result is attained by a series of co-operating influences. In the pigeon the hypnotic state cannot be induced by holding the bird upon its back and stretching the neck, as in the hen, neither by the procedure found successful in the smaller birds; but by affording an object to fix the attention of the eyes of the bird, the same result is attained.

This furnishes us with the third factor of the series of influences,—the fixation of the attention. Of course for this purpose it is not needful to employ the finger of

the experimenter: any inanimate object does just as well: so that it cannot be asserted that any "magnetic" influence is emitted from the person. Chickens can be thrown into this state by means of a piece of pasteboard cut into the form of a horse-shoe and hung over their comb, allowing the ends to come just in front of the eyes: they fall into a condition simulating sleep, in which their heads can be raised or lowered, remaining where placed, as if the neck were made of wax. From all this, two conclusions may be drawn: that by fixing the attention the cataleptic and hypnotic state can be produced, and that this so-called hypnotic state can be induced in animals,—a fact which has been suspected, and even asserted, but which has never been accurately examined into before.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

SURGICAL CLINIC OF PROFESSOR GROSS, M.D.

Reported by Edward L. Parks.

STRICTURE OF THE ŒSOPHAGUS.

THIS woman, 58 years old, has suffered from stricture of the œsophagus during the past two years. She is now unable to take any kind of solid food, and she is obliged to swallow liquids with the greatest deliberation, sip by sip, or they always at once regurgitate. It is six weeks since she has taken any solid food. She is losing flesh rapidly, and is so much weakened that she cannot perform the ordinary household duties. She has no pain, except occasionally in the back.

I shall now try to pass an œsophageal bougie, after having carefully oiled it. It descends a great distance without interruption, showing that the constriction is low down. I shall next try this prostatic catheter, which is longer and will pass through a smaller orifice. It, too, fails to enter the stomach. The examination merely reveals the fact that the œsophagus is tightly constricted at its lower extremity. Of its nature we cannot speak with certainty. Thirteen years ago Dr. W. H. Pancoast removed her left breast on account of scirrhus. The present trouble may be similar to that which attacked the breast, for it is well known that scirrhus often appears simultaneously in different parts of the body.

It is unusual to find an organic stricture so low down. Usually it is situated opposite the larynx. The disease may be carcinomatous, syphilitic, or caused by the presence of a foreign body, or the effects of lye. I show you the œsophagus of a child who drank from a cup containing lye. The stricture is so tight that not a drop of water can pass through. The child died emaciated to the utmost degree. A spasmodic stricture of the œsophagus is a very different affection from an organic one. It occurs in women oftener than in men, and is especially frequent in young girls of a nervous, irritable temperament. It may depend on dysmenorrhœa about the age of puberty, or upon affections of the womb at any period of life, upon spinal irritation, or indigestion. It often appears suddenly with a sense of suffocation. Antispasmodic remedies, as assafœtida, valerian, or Hoffman's anodyne, relieve it. It generally vanishes, as if by magic, at the simple touch of the bougie. The patient should guard against its recurrence, by careful attention to the general health.

The patient before us should make free use of milk punch, and take gentle exercise, when the weather permits, in the open air. Anodynes are not called for, because of her freedom from pain. Direct interference of any kind would be unjustifiable. Gastrotomy is sometimes employed in cases of this kind, of course only as a *dernier ressort;* but for such an operation the patient is utterly unfitted.

ORCHITIS.

This young man, 17 years old, has a swelling in the left testicle. The organ is the seat of a dull, aching pain, is tender to the touch, hot and hard, with a sense of weight, which is a common symptom of orchitis, especially of the acute variety. The man says he has never had venereal disease; and his statement derives plausibility from the fact that the epididymis is free from inflammation. The common cause of orchitis is gonorrhœa repelled by a cold or mechanical irritation, and then the disease usually begins in the epididymis, or, indeed, may be wholly confined to it so that it is rather epididymitis than orchitis. Another cause is direct violence; and it was doubtless the origin here, for the patient struck his testicle smartly in mounting a horse not long ago.

In all cases of orchitis, serum is effused into the vaginal tunic: hence a part of the treatment consists in drawing off the fluid by one or more punctures. This treatment is suited to the cases only in which the distention is considerable. Much of the hardness depends on effusion of lymph into the seminiferous tubes. Suspension is useful if done judiciously. I shall direct the application of a dozen foreign leeches, followed by a lotion of sugar of lead and powdered opium, dissolved in hot water and used cold. The diet should be strictly light; and a mixture of tartar emetic, epsom salts, and tincture of veratrum viride should be freely exhibited.

It may become necessary to give mercury, but it is not advisable to do so until this treatment has been fairly tried.

CYSTIC HYDROCELE OF CORD.

The boy now before you, gentlemen, is fifteen months old. There is a fulness, not in the scrotum, but in the groin, which has an elastic feel, but cannot be made to disappear by the pressure of my fingers. It is insensible and colorless, except that the tumor under the integument is slightly bluish. You are aware that congenital scrotal hernia is not uncommon; but that is not the case here, for it would have been noticed long ago, whereas the mother says she only noticed this swelling very lately. Hydrocele of the cord may be congenital, and may be associated with scrotal hernia. By making the tumor tense and inserting this exploring-needle, properly oiled, there is an escape of fluid, which establishes the diagnosis beyond doubt. Cystic hydrocele of the cord, then, is the trouble, a disease comparatively rare in children. It is to be treated precisely like that of the vaginal tunic,—by exciting inflammation and thus provoking an effusion of plasma.

EPITHELIOMA OF THE LOWER LIP.

You observe that the lip of this young woman is fissured and covered for the most part with an incrustation. There is a raw surface at one part, but no material hardening anywhere. She has no pain, but occasional itching. Her general health is poor, and she is inclined to be dyspeptic. The first thing to be done is to get rid of the scabs; and for this purpose I shall direct the application of a compress, wet with warm water, at night, to be followed by a lotion containing three drops of the officinal solution of acid nitrate of mercury to the ounce of water. Let her take, besides three grains of blue pill and one grain of ipecac daily, a mixture of Fowler's solution, corrosive sublimate, and tincture of the chloride of iron.

Her blood is deficient in red globules and fibrin. The iron will exert a tonic influence, and Fowler's solu-

tion and corrosive sublimate are each excellent alterants. We shall see her again, and if she is not much improved in two or three weeks I shall remove the offending portion of the lip by a V-shaped incision. She has evidently epithelioma, with a tendency to malignancy.

STONE IN THE BLADDER.

This man, kindly brought here by his physician, Dr. Weisse, is a farmer, 61 years old. He suffered originally from paralysis of the bladder, and during the last four years has been unable to pass his water without the use of a catheter. He now has recourse to that instrument many times in the day, and, according to his statement, from ten to twenty times in the night. He has constantly a burning pain in the bladder and urethra. The constancy and intensity of the pain may be appreciated by the fact that his medical attendant has been giving him daily five grains of morphia, in two doses, without obtaining sleep. Such is the tolerance of opium that pain produces. The urine is occasionally quite bloody. Flatus in the rectum increases the vesical irritability. His bowels are habitually constipated. Dr. Weisse informs me that the prostate is enlarged. This completes the history of the case; and we shall now look for further information by examination.

I introduce this sound, oiled and warmed. If you are very quiet, I think you can all hear the sound of the instrument as it strikes against a stone. I now insert my finger, oiled, into the rectum. The prostate is enlarged in its antero-posterior diameter, so that my finger cannot reach its farther extremity. It is plain that both the stone and the prostatic enlargement are of several years' duration.

The patient says that the pain increases immediately after the passage of water. There is in many cases of this kind a sense of relief at that time.

I shall not operate upon him to-day, because he travelled ninety miles yesterday in coming here, and therefore would ill bear the shock of an operation after so much fatigue. I shall order him, thrice daily, twenty grains of bicarbonate of soda, to obtund the morbid sensibility of the mucous membrane. Experience shows that this remedy is better than the bicarbonate of potash, though they are sometimes combined. He should be well fed, because he is old and weak. Milk punch or ale might be beneficial; though the latter would increase the flow of urine. Sydenham, the Hippocrates of his time in England, suffered with vesical irritability in the latter part of his life, and was much relieved by drinking ale, the lupulin of the hops exerting an anodyne influence.

NEURALGIA.

This man, 47 years old, suffered at one time from pain in the right side and shoulder, so much that he sought relief in one of our hospitals. He is now tormented constantly with sharp, shooting, burning pains in the testicles, especially the left, in the spermatic cords, the bladder, and, more rarely, between the shoulders and along the thighs. He has a scalding and bearing-down sensation on micturition, and he passes, he says, his water every five minutes in the day and night, a statement which is to be taken with some reserve. His bowels are constipated. He does not sleep, and he perspires profusely. He thinks he never fully empties his bladder.

In examining him in the same way that I did the previous case, I find a capacious bladder, not at all fasciculated, though I think there is some roughness at the upper end. The prostate is of natural size. I find no stone, but there may, nevertheless, be one; for, as I have tried to impress upon you, we may only find it after repeated failures to do so. There is a neuralgic element in the case, as is proved by the history of the case, especially by the fact that he felt pain first in the side and shoulder. The remedy I shall order consists of a combination of uva ursi and soda, the bicarbonate of soda to be added to the infusion of uva ursi after it is prepared.

Of this a tablespoonful and a half, four times daily, in a quarter of a tumbler of water, is to be taken. The uva ursi acts specifically on the bladder, and the carbonate of soda will obtund its sensibility. The patient should abstain from animal food and coffee, and should remain recumbent. He may use tea and milk freely. He is to take, also, morphia and quinia freely.

Fomentations are often useful in such cases; but I shall not use them here.

A New Method for Healing Ulcers (Dr. Nussbaum: *Wien. Med. Presse*, May 4, 1873).—The author claims to have successfully treated upwards of sixty cases of chronic, extensive, and otherwise intractable leg-ulcers, by the following simple procedure. It is at least worthy of a trial. The patient is first narcotized, and then around the ulcer of the leg or foot, a finger's breadth from its margin, an incision extending down to the fasciæ is made; numerous blood-vessels are divided, and a severe hemorrhage ensues unless a fine pledget of lint be packed into the cut and the entire ulcer strongly compressed. The packing with lint is also necessary to prevent union of the cut edges by the following day. Upon the second day the bandage and lint are removed; from then until a cure is effected a simple water-dressing is applied.

The author states that an astonishing change can be seen, even in the first twenty-four hours: the ulcer, which yesterday threw off quarts of thin, offensive, ichorous pus, furnishes to-day not more than a tablespoonful of thick, non-offensive, healthy pus. The old ulcer becomes rapidly smaller, healing from the margin towards the centre, and is healed in a short time, but the cut is changed into a broad circular sore, which also speedily cicatrizes.

The great diminution of the secretion, and other favorable changes occurring in the ulcer, find an explanation from the fact that the circumcision has divided dozens of large, abnormally widened blood-vessels. Time is thus given for the lessened nutritive material, which previously was carried off by the excessive secretion, to be transformed into cells and connective tissue; in other words, granulations are formed, which fill up and heal the deep ulcer.

Without claiming this as a radical method, the author assures us that the cure is much more rapid, and the cicatrix becomes more elastic and resisting, than in the ordinary means applied, which usually require so much time that the patients depart with half-cured ulcers, soon to find themselves in their previous deplorable condition.

Temperature as an Indication of Fœtal Life.—According to Cohnstein, the temperature of the uterus is a more certain indication of the life or death of the fœtus than either its movements or the beating of its heart. The fœtus has a higher temperature than the mother, and imparts it to the uterus; so that this organ is warmer than the axilla, or even than the vagina. If the child die, the temperature of the uterus falls to the level of that of the other parts of the body, and even, Cohnstein says, below this, as the dead fœtus abstracts heat from it. This fall of temperature becomes perceptible two or three hours after the death of the fœtus, and may be ascertained by introducing a curved thermometer a little way beyond the inner os uteri. In this way, also, the diagnosis between intra-uterine and extra-uterine pregnancy may be assisted.—*British Medical Journal.*

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 21, 1873.

EDITORIAL.

A PRACTICAL REFORMER.

MOST of our readers will remember the travail, some years since, of President Bergh, of New York, and of the Female Branch of the Pennsylvania Society for the Prevention of Cruelty to Animals, on account of the frightful tortures inflicted by the physiologists upon the lower animals. As the wicked physiologists have continued to torture the unfortunate dogs, cats, rabbits, rats, and other creatures in the lower ranks of life, it is to be hoped that time and usage have rendered these aforementioned philozooists less sensitive, and thereby relieved their sympathetic sufferings. Feeling, however, as we do for them, we hail with delight a prospect of relief. One Mr. Rusden, of Melbourne, Victoria, has read an essay before the Royal Society of the place, containing a proposition which does honor to his heart and head, and which will do away with all excuse for the unhallowed practices at present indulged in.

Being of a practical as well as of a philanthropic turn of mind, Mr. Rusden proposes to accomplish several ends at once. When his scheme is carried out, "the honest, starving poor will no longer be so mistaught as that crime will entitle to state maintenance, and solve all their difficulties," and "criminals, by being made to work for their support, will not compete with honest labor." Hence there is the solution of the vexed question, What shall we do with our criminals? The convicted persons are to be utilized as subjects for physiological, medical, and surgical experiments. For this purpose they are to be divided into three classes. 1. Those convicted of minor offences, who are only to be employed in testing the value of various forms of diet, or of such drugs as can cause but little pain or inconvenience. 2. Those guilty of serious offences, on whom graver experiments are to be practised, but in whom life is not to be risked. 3. Those convicted of the highest grades of crimes, in whom life is to be freely put in peril.

As already stated, the mind of Mr. Rusden is both humane and practical: humane, because, according to the new code, "no unnecessary pain shall be inflicted;" in fact, it will be generally indispensable to avoid it by means of anæsthetics; practical, since, he says, "a fourth advantage is the enormous reduction of cost in the final disposal of criminals which would obviously result; as all the worst criminals would be utilized for experiments involving so much risk or certainty of death as would speedily reduce their numbers. I believe that the present cost of disposing of criminals would be reduced far more than fifty per cent., and that the supply of subjects for experiment would soon fall far short of the demand." The enthusiasm of Mr. Rusden is quite contagious. We feel its influence, and sincerely hope that the legislature or house of assembly of Victoria will not fail to give the stamp of actuality to his suggestion. We shall watch with interest for the passage of the needful laws, and then, if it be not too late, shall apply for a position upon the well-paid medical staff appointed to carry out its provisions. Let us trust that the time is not far distant when troubled visions shall no longer haunt the sleep of rabbits, dogs, cats, and their congeners.

BABIES AND BEEF-TEA.

WE have long thought that the statistical patriots were on the wrong track in their perennial lamentations over the decadence of our native population, in so far that they are continually urging for the birth of more children. From our point of view it is much more decisive in the increase of a people how many infants live than how many are born. Moderate-sized families of strong, healthy, well-trained children we hold to be of much more value to the state than great litters of under-nourished babies,—early candidates for the grave-yard.

It is, therefore, with great pleasure that we see our Obstetrical Society, instead of fulminating anath-

emas, devoting its attention to the reduction of infant mortality. Under its direction there have been recently issued special rules for the management of infants during the hot season, in a little pamphlet, which ought to be, and we believe is to be, scattered broadcast throughout our city. When the summer's season is fairly upon us, we hope the committee will see that the rules are published in at least one of our daily papers.

The rules themselves are excellent, and worthy of the array of names by which they are signed. Unfortunately, in one of a series of receipts added to them there is a very serious misstatement, which, as it supports a popular error, and relates to an intensely practical point, suggests a comparison between the committee and the famous cow that gave a good pail of milk, etc.

We do not propose to insult the intelligence of our readers by offering proof that beef-extract and beef-essence contain at most only a homœopathic allowance of nutriment; yet constantly mothers, nurses, and, we may add, even doctors, are dosing with these preparations children and adults, under the delusion that they are feeding them,—a delusion which is already sufficiently chronic in most of the individuals afflicted thereby, but which we fear will be rendered hopelessly incurable by the assertion of this learned committee that beef-tea when made in accordance with a certain receipt contains the whole nourishment of the beef. There is undoubtedly a difference between beef-tea and beef-essence; but, as this is not distinctly stated in the pamphlet of the Obstetrical Society, the assertion alluded to will certainly confirm error in the mind of the popular audience to which the rules are chiefly addressed.

More to the point, perhaps, is the fact that the statement of the committee is very far from being true as regards beef-tea. The receipt may be found in another column of our issue. It is very evident that, when beef-tea is made in accordance with its directions, only such matters as are soluble in water are extracted from the meat, the fibrin, the muscular fibre, etc. being left behind, whilst the kreatinin, carnin, and other innutritious products of destructive metamorphosis, with the inorganic salts, are dissolved.

It is equally evident that the only nutriment contained in this Obstetrical fluid is albumen. We have had a pint of the beef-tea carefully prepared according to the receipt of the committee, and on adding to it nitric acid obtained precisely one hundred and ninety-one and a half grains of precipitate. The truth of the following formula consequently rests upon the official declaration of the Philadelphia Obstetrical Society: Albumen ʒiij = Beef one lb.

We do not mean in any sense to deny the value of beef-tea when properly used. We do mean to insist that as a food it is an extremely wasteful preparation, and that to tell the poor of the community that they are giving to their children all the nourishment of the beef in giving beef-tea is to practise unwittingly a great fraud upon them.

Moreover, we desire to call the attention of physicians to the fact that beef-tea contains so much potash that when given in large quantities it is a medicinal agent and can only be intelligently employed with a direct appreciation of this fact.

According to Lehman's analysis, a pound of beef contains about forty grains of potash; and, as this is all extracted by the water, the beef-tea of the Society contains at least one-fifth as much potash as albumen.

PROPYLAMINE.

THE amount of attention which this alkaloid is attracting in Paris and in London, and the assertions which are made of its novelty, strike us as being something extraordinary, seeing that it was tried more than ten years ago in this city for the very complaints—*i.e.* rheumatic troubles—in which it is now lauded abroad, and was found wanting. Whether it will prove more reliable now than it did then, whether it was used here in too small doses to be effective, we cannot tell. Those of our readers who desire all the information that is possessed of its action are referred to Guibourt's "Traité des Médicaments Nouveaux," second edition, 1865, and to an inaugural thesis published at Strasbourg, in 1870, by M. Fargier Lagrange, who speaks of it under the name of Trimethylamine. He claims that it "diminishes the intra-organic combustion, and lessens the elimination of urea; decreases the activity of the circulation, and lowers the temperature; and exercises a sedative action on the nervous system, manifestly diminishing the neuralgic and articular pains."

It is stated that the best results are obtained in the most acute forms of inflammatory rheumatism.

THE *New York Medical Journal* for June is mistaken in asserting that the Jefferson Medical College of this city failed in its effort to obtain a State appropriation last winter. As most of our readers, no doubt, know, the legislature granted it all that was asked for.

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

MAY 5, 1873.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

PRESENT, — Prof. J. Carson, and Drs. J. G. Hunt, F. W. Lewis, Tyson, Allen, McQuillen, Norris, Buckingham, and Richardson.

Dr. J. GIBBONS HUNT made a very interesting and useful verbal communication in regard to the use of extract of hæmatoxylon in the preparation of stainings of both animal and vegetable tissues. In the course of his remarks he stated that, after repeated experiments with the solution as recommended by Dr. J. W. S. Arnold, of New York, he had been led to modify the liquid by the addition of glycerin, which was found to render it much more satisfactory as a coloring material. The proportions which yielded, in his hands, the best results, were,—

Arnold's solution (of alum and ext. of hæmatoxylon),	f℥ss;
Glycerin,	f℥j;
Alcohol,	f℥j.

This fluid, which when poured out into a watch-glass for use should be perfectly transparent, resembles carmine in that it stains the nucleus of a cell very deeply; but it also faintly colors other portions of the cellular elements, of different degrees and tints. Like chloride of gold, it enables us to demonstrate the very finest net-works of non-medullated nerve-fibres running from nucleus to nucleus in the coat of an artery, and it possesses the great advantage over the auriferous salt, that after such staining of the nerve-tissue we can still study the ultimate structure of the nervous filaments.

Dr. HUNT observed that in vegetable histology hæmatoxylon had certain advantages over either aniline, carmine, or carthamus, among which he might mention the fact that when, as is too frequently the case, we overstain a specimen, this excess of color from hæmatoxylon may be in part removed by maceration in a weak acetic acid solution.

In conclusion, Dr. HUNT exhibited several exquisite specimens of hæmatoxylon stainings, and particularly invited a comparison of their value with that of a thin section from an example of cirrhosis of the liver from the Army Medical Museum at Washington.

After the meeting, Dr. HUNT also displayed the lines of dots upon a frustule of Pleurosigma angulatum under a $\frac{4}{10}$ inch objective, but magnified by the aid of an amplifier, draw-tube, and deep eye-piece 1800 diameters without serious loss of definition.

Dr. JAMES TYSON remarked that in his laboratory work, with the hæmatoxylon solution, as prepared according to Arnold's directions with alum and water, he had met with the same difficulties as his friend Dr. Hunt. Although he diluted the coloring liquid to one-fourth the strength recommended, he nevertheless found that specimens stained with it, whether mounted in oil of cloves or in damar, were ruined after a short time by the formation of octahedral crystals upon the under surface of the glass cover. In diluting the solution (Arnold's) with alcohol, he had several times found that a precipitate was formed; but this misfortune did not occur when water alone was employed.

Dr. HUNT suggested that the troublesome crystals which destroyed the value of these specimens were probably composed of alum, which, being insoluble in oil of cloves, was deposited on the surface of the glass.

REVIEWS AND BOOK NOTICES.

THE TREATMENT OF SYPHILIS WITH SUBCUTANEOUS SUBLIMATE INJECTIONS. By Dr. GEORGE LEWIN, Prof., etc. Translated by CARL PROEGLER, M.D., late Surgeon, etc., and E. H. GALE, M.D., late Surgeon, etc. Demi 8vo, pp. 249. Philadelphia, Lindsay & Blakiston, 1872.

The wide spread of syphilis among all classes, the dreadful suffering which it entails, and the proverbial tendency which it has to relapse, all combine to make the profession and the public hail with the utmost gladness any method of treatment which promises even a fair prospect of permanent cure. Hypodermic medication has assumed great importance within the last few years, and it is not at all strange that it has been proposed to treat constitutional syphilis in this way. Prof. Lewin has, probably, employed the method for a longer period and in a larger number of cases than any other living man, both in his private practice and in the Charité Hospital at Berlin. This fact gives his testimony an air of authority, and American physicians cannot but congratulate themselves that this work, notwithstanding its many short-comings, has been placed within their reach. The author, who claims to have originated this method of treatment, and to have introduced it into the Charité seven years ago, probably speaks of his results a little too enthusiastically; but his views are undoubtedly entitled to a careful consideration, especially as he tells us in his preface that he has treated more than two thousand patients by this method.

The injection is made in the usual way, and the author prefers to introduce the remedy beneath the skin of the subscapular and sacral regions. He selects these parts because he believes them to be less sensitive than others, and not because their power to absorb is greater. The injection seems to produce but little irritation, for, among one thousand patients treated by Prof. Lewin in private practice, he has had only one small abscess upon the fore-arm. This shows that the inconveniences to the patient cannot be very great; and indeed, according to the author's showing, they are not sufficient to form a reasonable objection to the treatment.

The local effects of this form of medication vary with the strength and quantity of the solutions employed. Prof. Lewin uses three of these: one three, another four, and the other six grains to the ounce of distilled water; and he injects from one-tenth to three-eighths of a grain of the remedy (p. 19).

In his description of the symptoms produced by the hypodermic injection of the medicine (p. 25) it is interesting to note that the ordinary effects of mercury are sometimes rapidly produced by the bichloride when it is administered in this way. It is evident from his own statements that these have been severe in some cases. The patients not only presented the ordinary symptoms of salivation, but when the dose was large the medicine acted as a powerful irritant, producing profound depression with symptoms of gastro-enteritis. The resemblance of "acute sublimate intoxication," as the author calls it, to the effects of corrosive sublimate when taken into the stomach, is very striking, and is almost sufficient to make one wonder whether the advantages of hypodermic medication are not somewhat overrated.

It has been said that salivation is produced with difficulty by the internal administration of the bichloride of mercury. This does not seem to be the case when it is administered by hypodermic injection; for many of Dr. Lewin's patients were salivated by it, since he states (p. 28) that mercurial stomatitis occurred in 144

of 256 women thus treated, and that in 79 of these the use of the medicine had to be stopped on account of the mouth-affection. We are not at all surprised at this, for the author certainly employs large doses of the drug. A considerable experience has led the writer to believe that few patients will bear much over one-twelfth of a grain, three times daily, by the stomach, while we find Prof. Lewin often gives three-eighths of a grain at a single dose. True, this is administered but once daily, as a rule; but the quantity seems to us to be large in proportion to that which should be used by the mouth.

This opinion is supported by the statements of the author, and a critical examination of the cases which he reports. He says (p. 26) the sublimate "often very quickly" salivates, and that he has frequently noticed the appearance of the symptoms of salivation "after a few hours only." As this effect does not promote but may rather retard the cure, we think that the dose should generally be smaller than those ordinarily injected by Prof. Lewin.

The results obtained by the author certainly appear to be very favorable to the administration of mercurials by hypodermic injection. His patients seem to have been relieved quickly, while among them relapses do not appear to have been so frequent as when the mercury is administered by the mouth or the patient treated by other methods.

We cannot dismiss the consideration of this work without saying something in regard to the manner in which the translators have done their part. Whenever a translated German book is put upon our table we expect to find it rather heavy, and with certain peculiarities of expression which are unavoidable. We are content now and then to pore over a sentence for some time to find its exact meaning; but even in these cases we expect to meet with good English. Such, however, is not true in the present instance. With a more sad jumble of bad grammar and atrocious language it has never been our fortune to meet; and, for the credit of our profession in this country, we hope that Prof. Lewin does not understand our tongue, and, if he does, for the sake of his own feelings we most sincerely desire that this execrable translation of his book may never fall into his hands. So poorly have these gentlemen done their work that the very first sentence in the book sounds most harsh, while the second is enough to make us close it forever. There is hardly a page in it that does not show the want of the proof-reader; whilst the volume is teeming with grammatical errors. These faults are bad enough in the work of an English author, but they detract much more from the translation of one the original language of which is somewhat peculiar and difficult at best to render into smooth English.

We do not consider the publishers blameless in putting this translation of Prof. Lewin's work before the medical public. The enterprising firm which issued it usually does things in good style. Of this book, however, they have every reason to be thoroughly ashamed. A few glances at the proof-sheets would have made them acquainted with the glaring literary errors of the translation. To see these, a professional education was not necessary; and if the book proves a financial failure they have themselves to blame. It will not be because it has no merit and was not needed, but simply because the English version of it has been so abominably prepared.

Conium in the Treatment of Insanity. By Daniel H. Kitchen, M.D., Assistant Physician of the New York State Lunatic Asylum.

In this article, reprinted from the April number of the *American Journal of Insanity*, the author strongly advocates the use of conium in cases of acute mania not dependent upon organic lesion of the brain, and especially in those cases characterized by unusual restlessness and muscular activity. He agrees with Harley in limiting the action of the drug to the motor centres, chiefly to the corpora striata, and does not attribute to it any direct hypnotic effect or any appreciable influence upon the secretions.

Quoting from Dr. J. W. Burman, who experimented at the West Riding Lunatic Asylum, he says, "Conia acting upon the purely motor centres in a sedative manner, and morphia acting in a similar way upon the sensori-motor and ideo-motor centres, it follows as a fair corollary that the combination of the two should lead to effects directly antagonistic to the condition of maniacal excitement; and, such being in fact the case, they may be thus used together with very great success in the treatment of cases of mania."

He details twelve cases of mania, arising from various causes, which were treated with conium, and in all of which its administration was followed by immediate and marked improvement and ultimate cure. In several of them bromide of potassium, chloral hydrate, and other nervines had entirely failed to relieve the wakefulness and excitement, which at once disappeared under full doses of conium. He has used it in epilepsy, hysteria, facial erysipelas, dysmenorrhœa, sciatica, etc., always observing the same results,—relief of motor irritability and consequent amelioration of the general condition. Of the different preparations he prefers the fluid extract, in doses of from twenty minims to one drachm, according to the motor activity of the patient, and has found the best vehicle to be ice-cold water.

The Treatment of Whooping-Cough with Quinine. By B. F. Dawson, M.D., Clinical Lecturer on the Diseases of Children in the Medical Department of the University of New York, etc., etc. New York, William Wood & Co., 1873.

In this little pamphlet, reprinted from the *American Journal of Obstetrics and Diseases of Women and Children*, the author reports eight cases of pertussis occurring in his practice and treated exclusively with quinine, administered according to the following rules:

"1. Give the quinine (sulphate or hydrochlorate) dissolved by acid in pure water only. For children under three years, from grs. v to grs. viii, and for older children and adults, from grs. x to grs. xii, to the ounce. 2. Give not less than a teaspoonful every single, or, at the longest, every two hours during the day, and whenever cough comes on in the night. 3. Give nothing afterwards for some minutes to destroy the taste or to wash out the mouth. 4. Continue giving it notwithstanding the first dose may be vomited. 5. Be sure that the quinine is pure and thoroughly dissolved."

He asserts that by following this plan he has rarely failed in promptly and completely removing the spasmodic element of the affection, the time required varying from one to twenty days. He supposes that the drug acts by attacking and destroying the "fungoid growth in the epithelium of the air-passages," which, with Prof. Letzerich, he believes to be the cause of the convulsive paroxysms of coughing. He also attributes some of the beneficial effects of the quinine to its sialagogue action, the increased buccal and salivary secretions softening and dislodging the accumulated mucus. For both these reasons he insists, as above, upon its administration in solution, and at short intervals, and accounts for its failure in previously reported cases by its having been given in large doses or in pills. The cough which frequently remains after the "whooping" has ceased must be treated as an ordinary bronchial catarrh.

GLEANINGS FROM OUR EXCHANGES.

On the Use of Artificial Respiration and Transfusion as a Means of Preserving Life (*British Medical Journal*, May 17, 1873).—Dr. T. Lauder Brunton, of St. Bartholomew's Hospital, presents, in an interesting and valuable paper, a review of various important physiological experiments and observations, and shows how they may be utilized in the treatment of disease. Quoting Huxley, he says, "Life has but two legs to stand upon,—the lungs and the heart; for death through the brain is always the effect of the secondary action of the injury to that organ upon the lungs or the heart." The experiments of the Abbé Fontana, Legallois, and Brown-Séquard have shown that headless trunks, isolated portions of the body, or the head alone, may be kept alive, or even restored to life, by a proper supply of oxygenated blood, and not only have nerves and muscles been made to retain vitality, but livers have secreted bile and lungs excreted carbonic acid hours after they were excised from the body.

A point of great practical importance is that the parts do not all die at the same time, and, as the brain and spinal cord generally die first, the heart may pulsate regularly after all respiratory movements have ceased and consciousness and reflex action are entirely lost. If, under such circumstances, respiration be kept up artificially, the heart continues beating, and the circulation of arterial blood through the brain may gradually restore its power, respiration recommence, and life be securely re-established. Schiff's experiments have demonstrated that animals may be kept alive, after almost entire destruction of the medulla, or after the injection of water under high pressure into the cranial cavity. Hence it is evident that we may hope for the best results from the use of artificial respiration in some of those cases of apoplexy where an extravasation almost instantly arrests the respiratory movements, either directly, by destroying a part of the medulla, or indirectly, by causing compression of the brain.

In poisoning by woorara, hydrocyanic acid, strychnia, etc., as well as by the bites of snakes, artificial respiration is invaluable as the only means of affording time for the excretion of the toxic agent. Where the poison exists in large quantities, or is excreted very slowly, requiring hours or even days before it can be got rid of, the obvious plan of treatment would be to remove the poison along with the blood in which it is circulating, instead of waiting for its slow removal by the emunctories; and here transfusion comes to the aid of artificial respiration.

Dr. Brunton details some cases where this method of treatment was followed by almost veritable resurrection. Alluding to the objections raised by Larry to the employment of lambs' or calves' blood when human blood cannot be obtained, he states that there is no physical reason why it should not be used, and concludes by remarking that "the risk of injuring a man's character, or that of his descendants, by transfusion of an animal's blood, is not for an instant to be weighed in the balance against the chance of saving his life in those cases where alone the operation would be performed."

Septicæmia and the Catheter (*British Medical Journal*, April 19, 1873).—Dr. David Ferrier, of King's College, in a short paper endeavors to show that the ammoniacal decomposition of the urine met with in retention is not the result of a fermentative action of the vesical mucus, but is attributable to the growth and multiplication of microscopical organisms, generally introduced during catheterization. To prove that urine in itself, apart from such contamination, is not liable to decomposition, he introduced a small quantity into a flask previously purified by heat, inserted a plug of cotton wool, and set it aside for a year, during which time it remained clear. The simple bringing into contact with the urine a surface not freed from germs, as an ordinary glass rod, was found sufficient to initiate ammoniacal putrefaction. He does not deny that in a catarrhal state of the urethra germs may gain access to the bladder precisely as spermatozoids pass through the cervical mucus in impregnation; but asserts that in ordinary conditions of the urinary passages the bladder is closed against them, and adduces cases where the introduction of the catheter was immediately followed by a change in the character of the urine, and subsequently by uræmic poisoning and death. Such cases are, of course, not those where the bladder can be readily and entirely emptied, but where, from atony, paralysis, or enlarged prostate, there is more or less complete retention of urine. He adds, that if the simple precaution were taken of using carbolic acid oil, instead of ordinary oil, for lubricating instruments passed into the bladder, we would have less cystitis and fewer cases of "surgical kidney."

Successful Transplantation of a Rabbit's Conjunctiva and its Adaptation to the Human Eye.—J. R. Wolfe, of Glasgow, reports the case of a foundry-man 31 years of age, where, in consequence of a severe burn from a mass of red-hot iron, there had resulted an extensive symblepharon, gluing the lower lid firmly to the ball in such a position that its ciliary border covered the upper edge of the pupil. Six weeks after the injury, when the inflammation had entirely subsided, Dr. W. dissected the lower lid from its attachments to the ball, and, to prevent its readhering, sutured on the raw surface thus produced the conjunctiva which he then dissected from the eye of a rabbit. (The animal was under the influence of chloroform, and the part selected was that covering the nictitating membrane.) The eye was dressed with dry charpie and a compressive bandage. On the day following, the transplanted conjunctiva had a grayish aspect, and warm fomentations were ordered. On the second day the eye was swollen and very painful, but the conjunctiva had lost its gray hue and become vascular. On the eighth day he was discharged cured, the eyeball freely movable and the transplanted conjunctiva healthy and adherent throughout. A few days subsequently, an iridectomy was successfully performed at the upper inner quadrant of the cornea, with the result of restoring him useful eyesight. The patient was seen two months subsequently, and the condition of the eye was still entirely satisfactory.

The author then gives a second, somewhat similar case, with equally favorable result.—*Glasgow Medical Journal*, 1873.

Albuminuria and Hæmaturia from Embolism in the Minute Blood-vessels of the Kidney (*British Medical Journal*, May 24, 1873).—Dr. George Johnson, of King's College, London, in a recent lecture on Bright's disease, alludes to valvular disease of the heart as a not infrequent cause of albuminous or even bloody urine by the production of renal embolism. The circulation through the renal capillaries being arrested, an albuminous and fibrinous exudation takes place into the uriniferous tubes, which subsequently becomes fatty and is absorbed, leaving a depressed cicatrix on the surface of the kidney.

Alluding to the uncertainty of the diagnosis of embolism in the renal vessels, he adds, "We may suspect the occurrence when, with the physical signs of aortic or mitral disease, without great impediment of the general circulation, the urine suddenly becomes albuminous or bloody. In some cases, extensive em-

bolism in one or both kidneys has been attended with severe lumbar pains, a scanty secretion of urine, and vomiting; but, when the obstructed portions of kidney are small, there may be no symptoms to indicate the occurrence of embolism."

The Tubercular Ulcer in the Larynx (Wahlberg: *Wien. Med. Jahrb.*, 1872, Heft 3, 238–247).—An examination of a large number of larynges of phthisical patients has led the author to the conclusion that the so-called tubercular ulcers of the larynx result from the disintegration of mucous or sub-mucous tubercles. Fine cuts of the mucous membrane hardened in chromic acid showed at the points of the most recent tubercles, which had only produced a prominence, and not a defect of the surface, a very fine, small-celled infiltration, which attained its maximum in the vicinity of the ducts of the mucous glands. After pencilling out these round cells, a net-work was seen, coarser and denser according to the age of the tubercle; its meshes, formed partly out of spindle-cells and partly out of a tough fibrous tissue, were scantily supplied with blood-vessels. The centre of this reticulum was taken up by a round heap of an opaque, finely granular mass, which the author, without giving any special characteristics, describes as tubercle.

As the more and more attenuated epithelial covering of the tubercle becomes destroyed and perforated, the tubercular ulcer is produced, whose basis is constituted by the progressively spreading destruction of the new cellular growth. Upon the edges of the ulcer are frequently seen papillary prominences of the mucous membrane, with cylinder-like proliferations of the epithelial covering.

Changes produced in the Liver by a High Temperature (*Lancet*, May 17, 1873).—At the regular meeting of the Pathological Society of London, Dr. Wickham Legge exhibited some microscopical sections of the liver of rabbits killed after an exposure of from six to twelve hours to a temperature of 105°. In all the animals the livers were found very dry, but little blood exuded from a cut surface, and the acini were indistinct. The liver-cells were filled with fine granular contents, so that in some cases the nucleus was invisible. Dr. Legge remarked that it was well known that parenchymatous degenerations of the liver were far more common than was formerly supposed. Excluding phosphorus-poisoning, acute yellow atrophy, and cases akin thereto, this finely granular condition of the cells had been chiefly met with where a high temperature had been noted; but no experimental proof whatever had existed that it was due to this cause. The cloudy swelling of the kidney in febrile diseases had long ago been noticed; but probably in patients dying from diseases attended with high temperature the liver suffers far more than the kidneys, and far more commonly.

Methylene Ether as an Anæsthetic (*British Medical Journal*, March 29, 1873).—Dr. J. O. Brookhouse details seven cases in which methylene ether was given as an anæsthetic. The average quantity required to produce insensibility was two and a half drachms, the average time between three and four minutes. In conclusion, he says, "It appears clearly, therefore, from these cases, that this ether is a direct paralyzer of the heart, and not certainly in any less degree than chloroform. This, indeed, so far as I can judge, is its only objection; whilst in many ways it possesses advantages. It is quicker in its action and time of recovery. Sickness, although almost always present, is not so persistent; and the patient does not complain of feeling so altogether 'seedy.' It does not blister the skin."

Extreme Depression and Paralysis produced by Hydrate of Chloral.—Henry J. Manning details (*Lancet*, May 17, 1873) two cases of monomania with exacerbations of excitement and obstinate sleeplessness, in which the administration of chloral was attended with very alarming symptoms. In one case, an elderly man, who had taken five grains twice daily and thirty grains on alternate nights for about two months, became so weak and depressed that he was unable to make the slightest exertion, and suffered from partial loss of muscular power in the lower limbs.

In another case, ten grains twice daily, with forty grains on alternate nights, produced in three weeks the same condition, with cold surface, fluttering pulse, and complete paralysis of the lower limbs.

In neither case was there any loss of sensation or any hyperæsthesia.

Liq. strychniæ was prescribed, and in a few days both patients regained their usual condition.

Sponge-tent in Epistaxis.—Dr. James Young (*British Medical Journal*, May 17, 1873) recommends the use of sponge-tent in cases of bleeding from the nose, and gives the following method of preparation: "Have a long piece of fine sponge, dipped in a solution of gum, compressed with twine, dried; and, after the twine has been unrolled, the sponge is thickly coated over with white wax. This is easily passed along the floor of the nostril, leaving a piece of red tape for extraction. The tent may remain for six hours, and must be gently rotated before extraction, to prevent fresh hemorrhage."

The Heart, in a Case of Poisoning by Arsenic.—Surgeon E. O. Tandy reports (*Indian Medical Gazette*, Calcutta, March 1, 1873) a case where a post-mortem made twenty-six hours after death, the subject being well nourished and in perfect preservation, disclosed extravasations of bluish blood in the muscular structure and columnæ carneæ of the left ventricle, with no signs of inflammation and a healthy endocardium. Death was subsequently found to have resulted from the criminal administration of arsenic.

Artificial Fibrin as a Dietetic Substance.—Dr. John Goodman (*British Medical Journal*, May 17, 1873) calls attention to a substance formed by exposing albuminous material, as an ordinary hen's egg, to the action of cold water for about twelve hours, and then boiling. He calls the product "artificial fibrin," and declares it to be unparalleled in its qualities of lightness, nutrition, and digestibility, and invaluable in cases of feeble alimentation where rejection of food forms a prominent feature.

MISCELLANY.

We are informed that Prof. Pancoast has resigned the chair of anatomy at the Jefferson Medical College. Dr. William Thomson, well known as the author of some highly original contributions to eye-surgery, has been elected to the position of clinical lecturer on diseases of the eye in the same institution.

Rules for the Management of Infants during the Hot Season.—*Rule* 1.—Bathe the child once a day in tepid water. If it is feeble, sponge it all over twice a day with tepid water, or with tepid water and

vinegar. The health of a child depends much upon its cleanliness.

Rule 2.—Avoid all tight bandaging. Make the clothing light and cool, and so loose that the child may have free play for its limbs. At night undress it, sponge it, and put on a slip. In the morning remove the slip and dress the child in clean clothes. If this cannot be afforded, thoroughly air the day-clothing by hanging it up during the night. Use clean diapers, and change them often. Never dry a soiled one in the nursery or in the sitting-room, and never use one for a second time without first washing it.

Rule 3.—The child should sleep by itself in a cot or cradle. It should be put to bed at regular hours, and be early taught to go to sleep without being nursed in the arms. Without the advice of a physician, never give it any *spirits, cordials, carminatives, soothing-syrups, or sleeping-drops. Thousands of children die every year from the use of these poisons.* If the child frets and does not sleep, it is either hungry or ill. If ill, it needs a physician. Never quiet it by candy or cake; they are the common causes of diarrhœa, and of other troubles.

Rule 4.—Give the child plenty of fresh air. In the cool of the morning and evening send it out to the shady sides of broad streets, to the public squares, or to the Park. Make frequent excursions on the rivers. Whenever it seems to suffer from the heat, let it drink freely of ice-water. Keep it out of the room in which washing or cooking is going on. It is excessive heat that destroys the lives of young infants.

Rule 5.—Keep your house sweet and clean, cool and well aired. In very hot weather let the windows be open day and night. Do your cooking in the yard, in a shed, in the garret, or in an upper room. Whitewash the walls every spring, and see that the cellar is clear of all rubbish. Let no slops collect to poison the air. Correct all foul smells by pouring carbolic acid or quicklime into the sinks and privies. The former article can be got from the nearest druggist, who will give the needful directions for its use. Make every effort yourself, and urge your neighbors, to keep the gutters of your street or court clean.

Rule 6.—*Breast-milk is the only proper food for infants.* If the supply is ample, and the child thrives on it, no other kind of food should be given while the hot weather lasts. If the mother has not enough, she must not wean the child, but give it, besides the breast, goat's or cow's milk, as prepared under Rule 8. Nurse the child once in two or three hours during the day, and as seldom as possible during the night. Always remove the child from the breast as soon as it has fallen asleep. Avoid giving the breast when you are overfatigued or overheated.

Rule 7.—If, unfortunately, the child must be brought up by hand, it should be fed on a milk-diet alone, and that, warm milk out of a nursing-bottle, as directed under Rule 8. Goat's milk is the best, and next to it, cow's milk. If the child thrives on this diet, *no other kind of food whatever should be given while the hot weather lasts.* At all seasons of the year, but especially in summer, there is no safe substitute for milk to an infant that has not cut its front teeth. *Sago, arrow-root, potatoes, corn-flour, crackers, bread, every patented food, and every article of diet containing starch, cannot and must not be depended on as food for very young infants.* Creeping or walking children must not be allowed to pick up unwholesome food.

Rule 8.—Each bottle-full of milk should be sweetened by a small lump of loaf-sugar, or by half a teaspoonful of crushed sugar. If the milk is known to be pure, it may have one-fourth part of hot water added to it; but, if it is not known to be pure, no water need be added. When the heat of the weather is great, the milk may be given quite cold. Be sure that the milk is unskimmed; have it as fresh as possible, and brought very early in the morning. Before using the pans into which it is to be poured, always scald them with boiling suds. In very hot weather, boil the milk as soon as it comes, and at once put away the vessels holding it in the coolest place in the house,—upon ice if it can be afforded, or down a well. Milk carelessly allowed to stand in a warm room soon spoils, and becomes unfit for food.

Rule 9.—If the milk should disagree, a tablespoonful of lime-water may be added to each bottleful. Whenever pure milk cannot be got, try the condensed milk, which often answers admirably. It is sold by all the leading druggists and grocers, and may be prepared by adding, without sugar, one teaspoonful, or more, according to the age of the child, to six tablespoonfuls of boiling water. Should this disagree, a teaspoonful of arrow-root, of sago, or of corn-starch to the pint of milk may be cautiously tried. If milk in any shape cannot be digested, try, for a few days, pure cream diluted with three-fourths or three-fifths of water,—returning to the milk as soon as possible.

Rule 10.—The nursing-bottle must be kept perfectly clean; otherwise the milk will turn sour, and the child will be made ill. After each meal it should be emptied, rinsed out, taken apart, and the tube, cork, nipple, and bottle be placed in clean water, or in water to which a little soda has been added. It is a good plan to have two nursing-bottles, and to use them by turns.

Rule 11.—Do not wean the child just before or during the hot weather, nor, as a rule, until after its second summer. If suckling disagrees with the mother, she must not wean the child, but feed it in part, out of a nursing-bottle, on such food as has been directed. However small the supply of breast-milk, provided it agrees with the child, the mother should carefully keep it up against sickness: it alone will often save the life of a child when everything else fails. When the child is over six months old, the mother may save her strength by giving it one or two meals a day of stale bread and milk, which should be pressed through a sieve and put into a nursing-bottle. When from eight months to a year old, it may have also one meal a day of the yolk of a fresh and rare-boiled egg, or one of beef- or mutton-broth into which stale bread has been crumbled. When

older than this, it can have a little meat finely minced; but even then milk should be its principal food, and not such food as grown-up people eat.

For the convenience of mothers, the following receipts for special forms of diet are given:

Boiled Flour, or Flour Ball.—Take one quart of good flour, tie it up in a pudding-bag so tightly as to get a firm, solid mass, put it into a pot of boiling water early in the morning, and let it boil until bedtime. Then take it out and let it dry. In the morning, peel off from the surface and throw away the thin rind of dough, and, with a nutmeg-grater, grate down the hard dry mass into a powder. Of this from one to three teaspoonfuls may be used, by first rubbing it into a paste with a little milk, then adding it to about a pint of milk, and, finally, by bringing the whole to just the boiling point. It must be given through a nursing-bottle.

An excellent food for children who are costive in their bowels may be made by using bran-meal or unbolted flour instead of the white flour, preparing it as above directed.

Rice-Water.—Wash four tablespoonfuls of rice, put it into two quarts of water, which boil down to one quart, and then add sugar and a little nutmeg. This makes a pleasant drink.

A half-pint or a pint of milk added to this, just before taking it from the fire, and allowed to come to a boil, gives a nourishing food suitable for cases of diarrhœa.

Sago, tapioca, barley, or cracked corn can be prepared in the same manner.

Beef-Tea.—Take one pound of juicy, lean beef,—say a piece off of the shoulder or the round,—and mince it up with a sharp knife on a board or a mincing-block. Then put it with its juice into an *earthen* vessel containing a pint of tepid water, and let it stand for two hours. Strain off the liquid through a clean cloth, squeezing well the meat, and add a little salt. Place the whole of the juice thus obtained over the fire, but remove it as soon as it has become browned. Never let it boil; otherwise most of the nutritious matter of the beef will be thrown down as a sediment. Prepared in this way, the whole nourishment of the beef is retained in the tea, making a pleasant and palatable food. A little pepper or allspice may be added if preferred.

Mutton-tea may be prepared in the same way. It makes an agreeable change when the patient has become tired of beef-tea.

Raw Beef for Children.—Take half a pound of juicy beef, free from any fat; mince it up very finely; then rub it up into a smooth pulp either in a mortar or with an ordinary potato-masher. Spread a little out upon a plate and sprinkle over it some salt, or some sugar, if the child prefers it. Give it with a teaspoon or upon a buttered slice of stale bread. It makes an excellent food for children with dysentery.

At a meeting of the Obstetrical Society of Philadelphia, held April 3, 1873, the undersigned committee was appointed "to consider the Causes and the Prevention of Infant Mortality during the Summer Months." The foregoing rules, drawn up by this Committee, were revised and adopted by the Society at a meeting held May 1, 1873, and ordered to be published.

Dr. William Goodell, *Chairman*,
Dr. J. Forsyth Meigs,
Dr. John L. Ludlow,
Dr. Albert H. Smith,
Dr. John S. Parry,
Dr. William F. Jenks.

The London *Lancet* says, editorially, "We have received a most touching proof of the great progress and the wide diffusion of sanitary science. It is in the shape of the circular of a candidate for the office of inspector of nuisances; and we cannot find in our hearts to withhold any portion of it from our readers. It runs thus:—

"'Sir,—Being a candidate for the office of inspector of nuisances, I beg to make a few remarks. Having for many years made the science of hygiene, or the guide to health, my especial study for the human family, I have been trying to carry it out; for in my rounds, which comprise a district of about twenty miles in * * * * * * as a hair-cutter, etc., among gentlemen's and farmers' families, I make it my duty to explain, whenever I have an opportunity, the importance of sanitary improvements, especially among the dwellings of poor people in crowded and ill-ventilated houses—almost forming districts of pollution—from which places mostly emanate miasma and effluvia producing blood-poison, which flies like fire, and ends in fever, smallpox, and other diseases, which is taken up and dropped by dews in healthy places, thereby producing endemic which sometimes ends in epidemic, almost as a plague, which was the case last year, puzzling even the faculty itself to know how it originated. I think those beautiful subjects ought to be the main lever or work of a sanitary officer's duty; and, if elected, I should do my utmost to rid places of the filth, and try more particularly to prevent surface-drainage (and this is most important) in places where many poor people have to get their drinking-water; I believe from this source emanate most of our fever cases.

"'At the election I should be most happy to be severely catechised as to my proficiency as a candidate.

"'Trusting to your vote, I beg to remain, sir, yours obediently, —— ——, Hair-dresser.'

"We need hardly say that we wish the gentleman every possible success in his candidature, and hope that his meritorious efforts for the good of his neighbors may for the future be continued with the advantages of official position and authority. Our only fear for him is that the officials at Gwydyr House may dread lest he should know too much, and may refuse to sanction his appointment out of consideration for the feelings of the gentlemen who might be called upon to 'inspect' his work. It is bad enough to have to deal with doctors who understand what they are about; but to have inspectors of nuisances of the same character would surely be more than Poor-law flesh and blood could bear."

CULTIVATION OF CINCHONA IN INDIA.—From the annual report made by Mr. George King, M.B., Superintendent of Botanical Gardens, and in charge of cinchona cultivation in Bengal, we glean the following particulars regarding the year's operations. During that period 166,285 plants of *cinchona succirubra*, and 44,500 of *cinchona calisaya*, have been added to the permanent plantation. Propagation has been carried on vigorously, the seed and nursery beds containing at least 600,000 young plants of the former and 147,500 of the latter species. The plantations of young trees have been thoroughly inspected, and weakly trees cut out. The bark from these, together with that obtained from the prunings of other trees, amounted to 116,000 pounds (equal to about 39,000 pounds of dry bark). Of this some 7000 pounds were sold at auction in London, realizing an average of one shilling and fivepence per pound. The total number of plants, cuttings, and seedlings at present growing on the plantation is 2,394,799. Of these two millions belong to *C. succirubra*, and the remainder to five other species. Regarding the cultivation of cinchona in India, Dr. King thinks its production as a crop cannot fairly be considered, as yet, beyond the condition of an experiment. "It has, indeed, been demonstrated that cinchona-trees can be grown successfully up to the age of about ten years, and that their bark is quite as rich in alkaloids as that obtained from the South American forests; but whether they will reach maturity remains to be seen. It is still to be settled how the bark crop can most advantageously be taken, and the respective merits of the systems of mossing as invented and practised by Mr. McIvor, of systematic coppicing, and of working forest-fashion by selection and thinning, cannot be determined without much additional experience. Connected with the commercial aspect of the matter, there are, as unsettled problems, the probable extent to which the price of the drug will be affected by the introduction into the European market of the large quantities of bark which must soon begin to be turned out by the various Indian and colonial plantations that have been established, the amount by which the demand for preparations of cinchona will be increased by the fall in their price which is almost certain to take place, and, finally, the advantages or disadvantages of the manufacture of an amorphous preparation at the plantation as opposed to the complete separation of alkaloid in a pure form, or to the more primitive plan of exporting all the bark to England and of taking prepared alkaloids in exchange as part payment."—*Canadian Pharm. Jour.*

MONTEVIDEO is again being decimated by yellow fever. Unadmonished by bitter experience or by the recent disastrous epidemic in Buenos Ayres, the inhabitants still allow cesspools to honeycomb the sites of their houses. They have fled in great numbers.

THE Sultan of Turkey retains the exclusive services of a lady physician—a New Hampshire lady, who graduated in Philadelphia—to attend the females and children of his household.

KILLED AT HIS POST.—Mr. Lutwidge, the Commissioner in Lunacy who, while visiting an asylum near Salisbury, was stabbed in the right temple by one of the patients, died on the evening of the 28th ult., a few minutes before the arrival from London of Sir James Paget. The fatal blow was inflicted with a long nail, and was followed by a paralytic affection, from which he never rallied.

WEEKLY RETURN OF DEATHS AND INTERMENTS IN PHILADELPHIA FOR THE WEEK ENDING SATURDAY, JUNE 14, 1873.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 10, 1873, TO JUNE 16, 1873, INCLUSIVE.

MEACHAM, FRANK, ASSISTANT-SURGEON.—Granted leave of absence for thirty days. S. O. 118, A. G. O., June 12, 1873.

SATURDAY, JUNE 28, 1873.

ORIGINAL COMMUNICATIONS.

CASES OF CEREBRO-SPINAL FEVER, WITH REMARKS.

BY JAMES H. HUTCHINSON, M.D.,
Attending Physician to the Pennsylvania Hospital.

DURING the last three months eight cases of this disease have been admitted into the medical wards of the Pennsylvania Hospital. Of these, six have proved fatal, one has ended in recovery, and one is still under treatment. The patient remaining in the ward is now fully convalescent, but the percentage of mortality has been so great, that there is reason to believe that the epidemic at present prevailing in the city, if not wide-spread, is very fatal in its character. The disease does not, however, seem to be confined to any particular locality, for the four patients who were under my immediate care, and whose histories I shall presently report, came from very different parts of the city. One had recently arrived from New York, and was taken sick on board ship. Another lived at Twenty-fourth and Lombard, a third at 315 South Seventh Street, and the last was attacked while at a sailors' boarding-house in the lower part of the city.

Most of the symptoms described by authors who have written upon this disease were present in the cases treated by me. In only one case, however, was there any eruption, and in this case, although said to have been distinct at one time, it was fading when the patient came under my care. The absence of the eruption in a large number of cases certainly justifies the abandonment of the name of spotted fever, by which the disease is even yet familiarly known. It is not, however, sufficient to authorize the removal of the disease from the class of general diseases to that of local inflammations: it is, therefore, satisfactory to find that the Committee on Nomenclature of the American Medical Association propose the name of cerebro-spinal fever, a name which at the same time indicates the general characters of the disease and the seat of the principal local lesions.

It is, unfortunately, too true that cerebro-spinal fever seems to be little amenable to treatment. In the first two cases quinine in twelve-grain doses was given, apparently without much effect upon either the pulse or temperature. The bromide of potassium, which was used in all the cases, seemed to have the power of diminishing the headache and restlessness, but exerted no further control over the disease. Opium in moderate quantities was resorted to in one of the cases, but its use was soon abandoned because it apparently increased the tendency to stupor. The most marked results followed the application of wet cups and of ice to the nape of the neck. In the single case in which they were used there was no subsequent complaint of pain. The long-continued use of ice is, however, not unattended with inconvenience; for after it had been applied for a few days the ears of the patient were found to be slightly frosted. In Case No. 4 ergot was prescribed, in the hope that, the inflammatory condition of the membrane of the brain and spinal cord having subsided, there remained only a congested condition of the vessels, which would be overcome by its use. Stimulus was ordered only when the general prostration of the system seemed to demand it. It was never given in the early stages of the disease. Remissions occurred in two of the cases. In the first case the subsidence of the febrile symptoms and of the pain, and the diminution of the mental hebetude, were so marked that I was twice led to believe that the patient was about to enter upon convalescence.

In the three cases in which death occurred and post-mortem examinations were made, in addition to the marked changes found within the cranium and spinal canal, alterations in color and diminution in consistence of the liver and spleen were very noticeable features; and this goes far to confirm the view that, while the lesions of the cerebral and spinal membranes are an essential part of the disease,—as essential perhaps as the pustular eruption in variola or the ulceration of Peyer's patches in enteric fever,—they do not in themselves and alone constitute the disease.

Case I.—Intense Headache—Violent Delirium—Retraction of Head—Death in Four Weeks—Injection of Membranes of the Brain and Spinal Cord.

P. G., æt. 28, born in England, a sailor, and unmarried, was admitted into the medical wards March 15, 1873.

The following history was obtained. About an hour or two before admission, he was seized with severe headache, and soon afterwards became violently delirious. He did not have a chill or convulsion. On admission the patient is semi-comatose, the pupils are contracted and do not respond promptly to light, and the neck is slightly retracted and rigid. He has fever, but a slow pulse, less than 60 in the minute. A loud but soft systolic murmur is heard over the heart, having its point of greatest intensity at the apex. There is no eruption of any kind visible. The urine, upon examination, was found to be acid, to have a specific gravity of 1036, to contain a trace of albumen, but no tube-casts.

March 16.—The patient was so noisy and restless last night as to make it necessary to remove him from the ward to the cells, and to strap him to the bed. His headache gives him the appearance of stupor, and renders him indisposed to be disturbed; but when roused he answers questions correctly, although slowly. The tongue is heavily coated with a soft velvety fur, but is moist; the bowels are loose, probably the effect of the croton oil given him by the resident physician who received him. The face is dusky, and the capillary circulation everywhere very sluggish. He was ordered twelve grains of sulphate of quinine daily, and twenty grains of bromide of potassium, three times a day, with a sufficient quantity of beef-tea.

March 17.—Cerebral symptoms unchanged; bowels are no longer loose. Neck still rigidly retracted. Restlessness continues. Tongue still heavily coated. Patient does not complain of pains in his limbs, and there is no marked hyperæsthesia of the surface.

March 19.—A marked improvement in the patient's

condition has taken place. He is perfectly conscious, but does not remember much about the beginning of his illness. The tongue has thrown off its fur. The headache has diminished in intensity, but the pain in the nape of the neck, and the rigidity, still continue; the retraction is, however, less. There is also a tendency to defervescence as shown by the thermometer.

March 21.—To-day the patient's temperature is normal, and the symptoms generally indicate that he is entering upon convalescence.

March 23.—The improvement noted on the 21st was of short duration. To-day the symptoms denote a relapse. There are marked mental hebetude, severe headache, and rigidity of neck. The pulse, which has hitherto maintained a certain degree of fulness and firmness, is to-day weak and compressible: it remains still infrequent. The heart-murmur still continues, with the same character as when first heard. The patient was directed to take three ounces of whisky daily.

March 25.—There is again to-day a fall in the temperature and a subsidence in the severity of the other symptoms. A tendency to constipation exists, to relieve which enemata are employed.

March 31.—All the previous symptoms have returned in full force; the mental hebetude, headache, occasional delirium, retraction of the head, and coating of the tongue, are as marked as before. The pulse, which has been up to this time unusually infrequent, is now over one hundred, and a very slight exertion is sufficient to cause an increase of from ten to twenty beats in the minute. The respiration still continues about normal. The use of the quinia was discontinued, and opium prescribed in grain doses every four hours.

April 8.—There has been little to note since the 31st ult. It is evident to-day, however, that the patient is gradually sinking. He lies upon his back, with his eyes half open; the stupor is more marked than it has ever been before, the tongue is still heavily furred, the pupils are moderately dilated and contract very slowly under the stimulus of light. No paralysis of the extremities. It is sometimes necessary to introduce a catheter to empty the bladder. Constipation continues. Decubitus dorsal.

April 13.—Death took place to-day at 12 M., having been preceded by the signs of congestion of the lungs. The autopsy was made twenty hours after death. Rigor mortis well marked. The dependent portions of the body were much discolored from hypostasis of blood. The blood was everywhere found fluid and dark in color.

The veins of the scalp were engorged with blood. The vessels of the pia mater were intensely injected, especially at the base of the brain. A large amount of serous effusion was found beneath the arachnoid and in the lateral ventricles. The translucency of the arachnoid was diminished at a few points, but there were only a few places where exudation could be found. The condition of the spinal vessels and membrane was the same as that just detailed. Several flakes of calcareous matter were found beneath the arachnoid and adherent to it. The heart was normal in size; the edges of the mitral valve were thickened, and it was not entirely competent to close the auriculo-ventricular orifice. The kidneys appeared to be healthy, but the liver was small, dark-colored, and soft, permitting the finger to be passed readily through its substance. The spleen was also soft.

Case II.—Delirium—Headache—Retraction of the Head—Faint Petechial Eruption—Recovery.

John M., æt. 17, born in Philadelphia, a cart-driver by occupation, and living near Twenty-fourth and Lombard Streets, was admitted March 19, 1873.

The patient's previous health has been good, except a slight attack of rheumatism, which did not confine him to bed. He was taken ill on the 11th inst., the first symptoms being violent pains in his temples and forehead, which were followed by high fever, nuchal pain and stiffness. He is said to have been very restless and delirious, but not violently so, and to have been the subject of hallucinations. His stomach has been very irritable; his bowels have been constipated. A faint petechial eruption was observed, two days after the beginning of his illness, on the face, abdomen, and limbs.

There have been occasional spasmodic contractions of the muscles of the arms, and shooting pains in the extremities. There has also been, it is said, a moderate amount of suffusion of the eyes.

On admission, the tongue is heavily coated; the pulse 90; the temperature 102°; and the respiration 24. Over the abdomen and on the inside of the thighs the traces of a petechial eruption may still be seen. The head is retracted, and there is still some headache. The urine is acid, and free from albumen; its specific gravity is 1024. The patient was directed to have quinia, gr. xii, daily, and bromide of potassium, gr. xx, three times a day.

March 20.—The patient's intellect is quite clear. There is no paralysis of the limbs, bladder, or rectum, and no marked hyperæsthesia of the surface. The temperature shows a tendency to fall, and there is every reason to believe that he is entering upon convalescence.

March 27.—On the 22d the temperature was normal; the quantity of quinia was reduced to six grains daily, and the use of the bromide discontinued. To-day the quinia is replaced by Basham's mixture and Linck's extract of malt.

April 11.—The patient has continued to improve since the date of the last note, and is to-day discharged at his own request. Since his admission a younger brother has died of the disease, at his own home, after only a few hours' illness.

May 20.—The patient has recently been heard from. He is in the enjoyment of his usual health, and at his former occupation.

For notes of the following case I am indebted to Dr. Frank Woodbury, one of the resident physicians at the Pennsylvania Hospital.

Case III.—Profound Coma—General Muscular Relaxation—Frothing at the Mouth—Death.

E. A., æt. 35, born in England, a sailor, and unmarried, was admitted into the medical wards of the Pennsylvania Hospital, April 16, 1873, in a condition of profound coma. The following history was obtained from his shipmates who brought him to the hospital:

On the evening of the 14th inst. he complained of pain in the head, from which he suffered all night. On the following morning he noticed, and called the attention of his companions to the fact, that he had lost the power of motion in the lower extremities. The intense headache continued, but little seems to have been done for his relief. At one A.M. of the 16th he became unconscious and began to breathe in a labored manner, white froth collecting about the lips. When first seen, the conjunctivæ were insensible to the touch; the pulse was full but very frequent; the respirations were stertorous, white froth still clinging to the lips; the skin was hot and moist, and exhaled a disagreeable odor, but there was no eruption. There was no rigidity of any of the muscles of the body. In the evening the pulse was 176, the respiration 42. The patient had been drinking for about a week previous to his seizure.

Death took place at four A.M. on the 17th, about sixteen hours after admission.

The autopsy was made twelve hours after death. Rigor mortis well marked; body large and well

formed. On the removal of the calvaria, numerous patches of plastic exudation were seen distributed over the surface of the hemispheres of the brain, under the arachnoid. Pus was found in the most dependent parts of the lateral ventricles, and at the base of the brain generally; a small collection had also taken place between the lobes of the cerebellum and under the arachnoid membrane. A band of lymph extended from the pons Varolii and crura cerebri to the adjacent parts. A layer of purulent lymph extended in streaks and patches along the posterior portion of the spinal cord throughout its entire extent. A few calcareous particles were found beneath the arachnoid.

Extensive pleuritic adhesion existed on the right side of the chest. The lungs were healthy. The heart was pale and contained in its cavities white fibrinous clots, but was otherwise normal. The liver and spleen were dark-colored and soft, breaking down readily under pressure. The kidneys were pale, the cortical substance being increased in thickness, apparently at the expense of the pyramids. About six fluidounces of urine were obtained from the bladder. This was found to be neutral in reaction, to have a specific gravity of 1034, and to contain albumen and granular casts, but no blood-disks. About half a pint of a dark grumous fluid without offensive odor was discovered within the stomach, which, with the exception of some ecchymotic patches on its mucous membrane, was healthy.

Case IV.—Intense Headache—Occasional Delirium—Great Hyperæsthesia—Subsequent Paralysis of the Extremities—Bed-sores—Death.

J. L., æt. 33; born in England, and living at the time of his seizure at 315 South Seventh Street, in this city; an unmarried man, and a paper-hanger by occupation; was admitted into the medical wards April 15, 1873.

The patient's previous health has always been good, and he is able to give us a good family history. Thirteen years ago he contracted a chancre, but he has never had any constitutional manifestations of syphilis. About thirteen weeks before admission he was taken, while living in a malarious district, with chills of the tertian type, which continued for five weeks. On the 9th inst., a week before he came under my care, he had a severe chill, followed by severe frontal headache, fever, and vomiting. His bowels have been constipated.

On admission, the patient walked into the ward. He is suffering from marked mental confusion and severe headache. His neck is rigid, and his head somewhat retracted; he has no pains in the abdomen or extremities; his tongue is furred, especially in the centre. The irritability of the stomach has passed off; the constipation continues. There is no distention of the abdomen, and no eruption of any kind discoverable on any part of the body. The pulse is slow, 56 in the minute; the first sound of the heart somewhat prolonged, but no murmur is heard over any part of the heart. The urine is acid in reaction, has a specific gravity of 1024, and contains a trace of albumen. He was ordered cut cups to the nape of the neck, ice to the back of the head, six grains of sulphate of quinia daily, and twenty grains of the bromide of potassium every four hours; beef-tea to be given freely.

April 18.—The patient evinces the same indisposition to be disturbed which was so marked a feature in Case I: he answers correctly, however, when thoroughly roused. Pupils moderately dilated, but contract fairly when exposed to the light. There is no suffusion of the eyes, but a slight degree of photophobia exists. The urine is dribbling away from him, but there is no accumulation in the bladder. Many of the symptoms have increased since his admission,—notably, the mental hebetude, retraction of the head, and the coating of the tongue. On the other hand, the headache has been entirely relieved by the cupping, by which about twelve ounces of blood were removed. The slightest movement of any of the limbs gives rise to great agony. There is no spasmodic contraction of the muscles, but reflex sensibility is much exaggerated, while the power of voluntary motion is much diminished.

April 20.—The patient to-day can move the right leg a little, but not the left,—which is exactly the reverse of what was noticed yesterday. Movement of the limbs still continues to cause great pain, and tickling the soles of the feet is evidently acutely felt, and gives rise to reflex movements, most marked on the right side. It is difficult to say whether the inability to move the legs comes from loss of power or from dread of pain. The patient refuses all nourishment. The pulse is more frequent,—84.

April 21.—The patient has less control over the left side of the body than the right, the face even being drawn to the right, and the tongue, when protruded, turning to the left. The left pupil is larger than the right, but responds slowly to light.

April 23.—An improvement in some of the symptoms is noticed to-day, especially in the mental condition of the patient, who now makes an effort to answer questions. He can move his left leg slightly to-day. A bed-sore is forming over the sacrum. The bromide was stopped, and whisky ordered.

April 26.—The neck continues rigidly retracted. The photophobia is less marked. The pupils are equally dilated and respond more promptly to light, intelligence becoming clearer. There is no headache. The pulse is very feeble and frequent. Numerous bed-sores have formed in the neighborhood of the anus, and at other points where the skin is subjected to pressure. The glans penis is much inflamed in consequence of the constant dribbling of the urine. The bowels, which have up to this time been only moved by enemata, are now loose, and occasionally the patient has an involuntary evacuation. The left fore-arm is becoming rigidly flexed.

May 6.—A few days ago the use of the quinia was discontinued, and the fluid extract of ergot, in doses of twenty minims three times a day, which was subsequently increased to five times, was prescribed. During the last week both fore-arms have been strongly flexed upon the arms. The patient cannot move the left fore-arm, and the right is moved only to a very limited extent. He has no power to move either leg. The paralysis of the face has disappeared. In spite of constant attention, the bed-sores have increased in number and size, that over the sacrum having laid bare the bone. To prevent any further sloughing, he has been placed upon his face.

May 10.—Hemorrhage occurred to-day from a bed-sore seated over the trochanter of left femur, and before it could be arrested it was necessary to tie a small artery. Although the patient presents a pitiable spectacle to-day in consequence of his numerous bed-sores, there is evidence, from the subsidence of the pains, from the diminution of the paralysis, and from the return of control over the bladder and rectum, that he is improving, and that, provided he does not sink from exhaustion, recovery is possible.

May 18.—The bed-sores present a healthy appearance; a few have, unfortunately, formed upon the anterior surface of his body. A water-bed has been procured, upon which he is now lying. He takes a fair quantity of nourishment, which he appears to enjoy. At his own request, the whisky was a few days ago substituted by ale, of which he drinks a quart every day. Pulse is frequent; generally in the neighborhood of 120. The tongue is clear; the bowels are regular, and under his control. The ergot is replaced by the following prescription:

℞ Strychniæ sulph., gr. $\frac{1}{18}$;
Acid. phosphor. dil., ℥x;
Elix. cinchonæ, f℥ss,

Four times daily.

May 20.—When the patient makes a strong effort of will, he can cause contraction of almost all the muscles of the extremities, but he is unable to move either leg from the bed. He has more control over the arms, but the movements which he is able to execute with these are slight. The contraction of the fore-arms upon the arms still continues. His mind is clear, but, although possessed of a fair degree of intelligence, he is unable to give a very clear account of the circumstances attending the commencement of his illness. He is of cheerful disposition, and bears his suffering with fortitude.

There has been at no time during his long illness any paralysis of sensation, the patient always correctly indicating the part touched.

June 16.—The patient lived until to-day, when he sank from exhaustion. The temperature continued high until his death.

June 17.—Post-mortem examination ten hours after death. The body was very much emaciated. Numerous bed-sores were distributed over the chest, sacrum, trochanter, and right knee; the sacrum being exposed. Rigor mortis was present and well marked.

Thorax.—The right pleural cavity contained a small amount of serum, and there were a few bands of freshly exuded lymph. The lung was very pale anteriorly and consolidated posteriorly. On section, the color was reddish-gray, and a fragment sank in water. At left apex there were a few old adhesions; the tissue of left lung was crepitant throughout.

Heart.—Pericardium was healthy. The heart was covered with a good deal of fat. The left ventricle was distended with a soft dark clot; the right auricle contained a white, fibrinous clot. The valves were healthy. The pulmonary artery contained dense white clot.

The stomach was healthy; the liver was pale in color and small; the gall-bladder was filled with yellow bile; the spleen was small, pale, and flabby, and the kidneys were normal in size, but flabby and rather pale. Their capsules were thickened, opaque, adhesive in places; the cortical portion was increased in thickness, but presented no other unhealthy appearance. The surface was marked with stellate veins.

Head.—Some fluid escaped on opening the skull, and still more when the brain was removed from the membranes. The dura mater was slightly congested; the arachnoid membrane covering the hemispheres had lost its transparency, especially anteriorly, and the fissures between the convolutions were filled with gelatinoid matter. At the base the injection of the vessels of the pia mater was more marked than on the convexity, and the opacity of the arachnoid less marked; the margins of the middle lobes were tightly adherent to the anterior lobes; the arachnoid around the medulla and the upper end of the cord was decidedly opaque and thickened. Outside the dura mater of the spinal cord there was a mass of gelatinoid matter very much resembling fat, but uniform in consistence, and evenly covering the membrane. This condition was most marked in the upper dorsal region. The two surfaces of the arachnoid were adherent in places. There was a deposit of lymph on the lower part of the cord on its posterior aspect, and a few calcareous plates were also found. The vessels of the pia mater were much injected.

A curious result of the post-mortem examination was the finding of the calcareous flakes beneath the membranes of the spinal cord. When these were treated with nitric acid, they were partially dissolved, with the evolution of carbonic acid. A small gelatinous mass was, however, left after the disengagement of the gas.

The following is the record of the temperature, respiration, and pulse in three of the cases:

Case I.—Philip G.

LOCAL CONGESTIONS IN A CASE OF AGUE.

BY H. G. LANDIS, M.D.,

Niles, O.

THE following case is one of some interest, as exhibiting some of the congestive phenomena of intermittent fever, and is reported not for its unusual character, but as illustrating certain points in the clinical history of the disease.

August 1, P.M.—Called to see M. J., æt. 40, intemperate, but a strong, vigorous man. His history was to the effect that he had been drinking excessively but had to-day stopped abruptly. He was alternately sitting and reclining on a lounge, and was delirious. The delirium was not violent, but cheerful, save that he required considerable persuasion to induce him to remain in the house. His skin was of natural warmth and moisture. Pulse full and slow—60 to the minute; tongue smooth and moist; slight tremor of the hands. There was no history or evidence of an antecedent chill. He was ordered chloral, gr. x, potassii bromidi, gr. xv, every hour until he slept.

August 2, P.M.—Has felt well all day, having completely recovered from all of yesterday's symptoms.

August 3.—At sunrise, while a heavy dew was on the ground, he went into his garden to weed. At 11 A.M. he had a *slight* chill, followed by fever. Called to see him at 3 P.M. Complains of violent headache, and pain in the chest, with cough. Eyes suffused; skin pungently hot. Pulse 90 per minute, quick and hard. Respiration hurried. Expectorates white mucus. On auscultation found exaggerated vesicular murmur over lower half of each lung, and distinct râles over base of right lung anteriorly. Applied mustard to chest, and gave tinct. verat. virid. ℥iij, to be repeated in three-quarters of an hour, and again in three hours.

August 4, A.M.—Found, much to my surprise, that, having rested well during the night, he was now in his usual state of health. No trace of trouble remained in the lungs. Skin moist. Eyes clear. Pulse 54. On the following day he had a severe chill at 10.30 A.M. which lasted a half-hour, and was followed by fever. Quinine was at once given, with arsenic and iron, and he had no further return of malaria.

As regards the first attack, I am still unable to see why there should have been, under the circumstances, any need of a differential diagnosis between delirium tremens and ague; and yet, in view of the subsequent phenomena, it may justly be questioned whether the patient had delirium tremens, and whether the delirium was not merely an evidence of a congestion of the brain caused by the paroxysm of ague. So far as my own observation extends, the chill of ague is never so marked when the internal congestion accompanying it is limited to a particular organ, as it is when the congestion is more generally diffused. I have seen a case where the patient became comatose at once without any chill at the time, the paroxysm seeming to expend its whole force on the brain. To this class, perhaps, belong the malarial neuralgias, and the pleuritic and other pains of the "dumb ague," where the attack is not in sufficient force to cause that general internal congestion which constitutes the chill, and causes instead local congestion, manifested by pain in the affected structure.

In the second attack the chill was slight, and yet the paroxysm was so violent as to cause sufficient congestion of the lungs to develop a crepitant râle. There is, however, an unknown factor in this problem. The intensity of the chill is practically no guide to the force or extent of the congestion. There is evidently a subjective disposition which determines this. Coma occurring in a paroxysm of intermittent fever is not an evidence of "pernicious fever;" for the same cause will give the patient's neighbors simple intermittents. It merely shows a pernicious disposition in the patient to a violent local congestion in place of the more general form.

June 2, 1873.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. ALLEN.

Reported by J. WM. WHITE, M.D., Resident Surgeon.

SYPHILITIC ULCERATION OF THE LARYNX—DYSPNŒA—TRACHEOTOMY—DEATH.

ELIZA FLEMING, æt. 46, was admitted to the hospital wards on April 18, suffering from dyspnœa, which was found on laryngoscopic examination to be caused by an ulceration of the left vocal cord. She was a victim of constitutional syphilis, and had at the time osteocopic pains, periosteal nodes, and other manifestations of the disease.

Treatment was commenced at once by the daily application to the ulcer of a sixty-grain solution of nitrate of silver, the use of atomized inhalations of muriate of ammonia and morphia, and the administration of large doses of iodide of potassium. She seemed for some time to be improving under this treatment, but at about half-past five on the morning of May 22 she was discovered by the nurse to be insensible, breathing with great difficulty and apparently in the last stage of suffocation. I was immediately sent for, and on reaching the patient found her entirely comatose and almost pulseless, with cold extremities, distended jugulars, and intense cyanosis. Reflex action was completely abolished: the heart-beats were so frequent that it was impossible to count them, and the respiratory efforts were faint, gasping, and incomplete, occurring only about eight or ten times a minute.

As the necessity for prompt action was evident, I immediately performed tracheotomy and inserted a tracheal tube. No difficulties were met with during the operation, and not more than twenty or thirty drops of blood were

lost. Improvement commenced at once: her respirations increased in frequency and fulness, the pulsations of her heart became firmer and more regular, and in half an hour she was breathing thirty-eight times a minute, with a pulse of 150. Her conjunctivæ now responded to irritation, but she still had paralysis of the left side of the face, which continued for thirty-six hours.

She was then carefully removed to a separate apartment, the temperature of which was raised to 80°, and a stream of the vapor of lime-water from an atomizer was directed towards her face and neck. She breathed entirely through the tube, no air whatever passing through her mouth or nostrils.

About eight o'clock, two hours after the operation, an accumulation of mucus in the trachea caused her pulse and respirations to run up in frequency and her inspirations to become shortened and labored. The administration of a tablespoonful of whisky-and-water, which was swallowed, brought on, as was desired, a fit of coughing. The mucus was expelled through the tube, and the condition again improved. At nine o'clock her pulse was 120, respirations 27. Injections of milk and whisky were given at short intervals, and at about ten o'clock she for the first time showed signs of consciousness, opening her eyes when spoken to. Pulse 120, respirations 22. At 10.30 she had a very severe spell of coughing, during which the tube was ejected from the trachea, together with a large quantity of bloody, tenacious mucus. An additional quantity of the same material was brought away by the introduction of a finger into the trachea, and the tube was then replaced.

During this paroxysm the cyanosis, which had almost disappeared, returned; consciousness was again lost, the pulse ran up to 132, and the respirations to 42, becoming incomplete. She continued in this condition, with marked congestion of the face and neck, until 12.30, when she once more showed signs of consciousness, and the cyanosis began to diminish. Pulse 129; respirations 33, and somewhat fuller. She had been taking hourly an ounce each of whisky and milk by the rectum. When it was necessary to excite coughing to effect the expulsion of mucus from the trachea, a spoonful of whisky by the mouth was always found to have the desired effect. Her general condition improved during the day; cutaneous sensibility returned, the cyanosis disappeared, and she showed a disposition to talk rationally. The pulse remained about 120, and the respirations from 22 to 24 per minute.

At 6.30, in a paroxysm of cough, the tube was again expelled, but on this occasion there seemed to be none of the dyspnœa which was observed when the same accident occurred previously, and it was discovered that she was breathing partly through her mouth. The tube was replaced without any trouble, by using the forefinger as a guide to the edge of the tracheal opening.

She was taking at this time a half-ounce each of whisky, milk, and lime-water, and from one to two ounces of beef-tea, on alternate hours. As there was some irritability of the rectum, most of these doses were given through the mouth, and were accompanied by more or less coughing, which seemed rather to relieve the patient than to exhaust her. The mucus which was discharged now was much less tough and tenacious than it had been, and was becoming slightly purulent.

Deglutition apparently gave her a great deal of pain; but we discovered that we could diminish the difficulty of the act by gently bringing the internal extremity of the tube towards the anterior tracheal wall, thus probably removing its pressure from the œsophagus. She slept quietly through the night, taking without any trouble the nourishment and stimulus which were given, and appearing when awake to be perfectly conscious and rational. Skin moist and warm. Pulse 120, respirations 26.

23d.—Beef-tea and the mixture of milk, lime-water, and whisky were given hourly during the day. The patient's condition remained about the same, with perhaps a little failure in strength, and a slight tendency to drowsiness, verging on stupor. The pulse was still 120, respirations 25 to 30. She expectorated frequently, bringing up large quantities of mucus, now decidedly purulent. Towards night she grew uneasy and restless, her respirations became jerking and irregular, and ran up to 42 per minute. Pulse 134. Return of the venous congestion of the face and neck.

At this time a portion of the food which was given her through the mouth began to be returned through the tracheal tube after an attempt at deglutition. This was at first attributed to a paralysis of the glottis and epiglottis permitting the liquids to trickle through the larynx and into the trachea; but it was subsequently found that the more probable cause was an extensive œdema of the posterior laryngeal walls, which by occluding the œsophagus forced the food into unnatural channels. It was still impossible to nourish her through the rectum, as even the smallest quantities of the most unirritating substances were at once rejected.

24th.—Early in the morning several severe coughing-spells greatly exhausted the patient; her pulse attained a frequency of 142, and her respirations became gasping and irregular. Once or twice during the day she seemed to rally and gather strength; but, in spite of the injection of large quantities of stimulus and concentrated nourishment, she sank again, her pulse became dicrotic, her breathing incomplete and limited to a small area over the upper part of the chest, and her skin cold and clammy. Coma returned, involuntary evacuations from the bladder and rectum took place, and the purplish hue of the face and neck steadily deepened. She died at noon on the following day, 25th, having survived the operation seventy-eight hours.

Post-mortem Examination—Brain.—General œdema of the brain-substance, and slight congestion of the membranes, with a large serous effusion beneath them and into the ventricles.

Lungs.—Extensive hypostatic congestion of the posterior surfaces on both sides, but no evidences of pneumonia or even of bronchitis.

Kidneys.—Large, white, and fatty, with diminution of cortical substance, especially on left side.

Liver.—Hardened, enlarged, and irregular, with evidences of chronic interstitial hepatitis.

The rest of the abdominal and thoracic viscera were healthy.

On opening the larynx, a large elliptical ulcer, some four or five lines in width, was found on the left side, extending along the vocal cord from the receding angle of the thyroid to the base of the vocal process, which was ulcerated and necrosed. The vocal cord of the right side, the false vocal cords, and the ventricles of Morgagni were healthy, and there was no involvement of the epiglottis. The mucous membrane on the posterior laryngeal walls was highly œdematous, and was filled with an effusion of semi-plastic lymph.

As syphilitic disease of the throat usually spreads from above downwards, and ulceration with partial destruction of the epiglottis is so constantly a forerunner of laryngeal ulceration, its entire freedom from involvement in this case is an interesting feature.

The probable cause of death was the cerebral œdema.

Treatment of Diabetes by Arsenic (*La France Médicale*, March 19, 1873).—M. Devergie recommends the employment of an arsenical treatment in cases of diabetes, and has satisfied himself of its good effects even when no restrictions were laid upon the diet and farinaceous articles were freely taken.

TRANSLATIONS.

BLOOD-LETTING.

THE following, from a very recent number of the *British Medical Journal*, has seemed to us of sufficient importance to be worthy of a prominent place in our issue:

"We gladly welcome such researches as have been lately published by Bauer in the *Zeitschrift für Biologie*, whose experiments were made for the purpose of discovering what changes occur in the metamorphosis of albumen and fat in the body after venesection. One would expect *a priori* that the withdrawal of a quantity of blood, by merely lessening the amount of albuminous substances in the body, would be followed by a diminution in the daily metamorphosis. So far from this being the case, however, Bauer finds that the quantity of albuminous bodies decomposed daily in the organism is invariably increased by blood-letting, and the excretion of the urea which is formed by their decomposition is consequently augmented. Notwithstanding this, however, much less oxygen is consumed than before, so that the substances into which albumen splits up cannot undergo such perfect combustion as before the venesection. One may readily understand this, for it is the red blood-corpuscles which carry oxygen throughout the body; and when their number is lessened by blood-letting, combustion in the tissues can hardly go on so rapidly as before. The decomposition of albumen in the body is altogether independent of the oxygen consumed in it. Now, fat is one of the substances formed by this decomposition; and, as its formation is increased and its combustion lessened, to say nothing of the fat taken as food, it must accumulate in the body: and this it actually does, as was well known to the phlebotomists of former days, whose writings contain many a record of cases where patients became enormously fat after copious blood-lettings. The same thing is seen in a milder form almost every day in the case of chlorotic girls, on whose bodies fat becomes deposited, because they have too few red blood-corpuscles to carry to it the oxygen required for its combustion. In many localities, too, cattle-breeders have become acquainted with the fact, and they increase the quantity of fat formed by their animals either in the shape of butter yielded by their milch-cows, or accumulated on the bodies of the oxen they wish to fatten by bleeding them from time to time.

"In diseases such as pneumonia, blood may be drawn for the purpose of diminishing temperature or of lessening dyspnœa. It may be supposed that Bauer's experiments support the use of blood-letting for the former purpose; but this is not the case, for the fall of temperature which blood-letting produces takes place immediately, and is soon over, while combustion does not diminish till some hours have elapsed. The fall of temperature is, therefore, due to another cause,—viz., the relaxation of the superficial vessels allowing the blood to cool more readily; but temperature can be reduced much more quickly and effectively by the cold douche or a wet sheet; and increased transformation of albumen, with diminished oxidation, is not unlikely to lead to a fatty degeneration of important organs.

"The relief which venesection generally affords in dyspnœa probably depends in part on its effect in cooling the body, for Fick and Goldstein have shown that increased temperature of the blood is sufficient to produce dyspnœa. This is a real benefit; but it would be attained as well by the use of the wet sheet, and a second cause of the subjective relief after blood-letting is by no means so desirable. The loss of blood, according to Traube, diminishes the irritability of the medulla oblongata, which is the centre of innervation for the respiratory muscles, and, by thus producing a sort of narcosis in this part of the nervous system, deprives it of its power to appreciate rightly the respiratory wants of the body. A third way in which it may prove useful in dyspnœa is by lessening the resistance, which hinders the right ventricle from emptying itself completely, and, by thus facilitating the circulation in the lungs, may assist respiration. The author considers that this condition will only last until as much fluid has been absorbed into the vessels from the tissues as will restore the blood to its former volume; but of this we are not quite sure.

"Lastly, he says it is not to be denied that the danger arising from serous exudations in important organs, as well as of congestion of the brain or lungs, may be temporarily averted by general blood-letting, in consequence of the absorption of fluid into the vessels which it occasions. This observation has been too often made to leave any doubt upon the subject; but as often has it been noticed that the danger of these conditions recurring increased after every venesection. Œdema is to a great extent dependent on weakness of the vaso-motor nerves (see this Journal, June 15, 1872, p. 644); and, this weakness being increased by blood-letting, the œdema is of course more likely to recur. Bauer, however, gives a case which shows most strikingly the immediate benefit produced by blood-letting in a case of œdema of the lungs; and we are inclined to think that the weakness of the vaso-motor nerves which might lead to a recurrence of the œdema might be successfully combated by a vaso-motor tonic, such as digitalis. While this shows that immense benefit may be derived from its use in proper cases, the effects which it produces on the tissue-change in the organism teach us that it is not a remedy to be thoughtlessly used, but one which must be employed only after due consideration and with watchful care."

AN IMPROVED TONSILLOTOME.

THE instrument represented in the accompanying cut was suggested by Dr. J. S. Billings, assistant-surgeon U.S.A., to D. W. Kolbe, Philadelphia, and was ordered for the Medical Department of the Army.

The advantages claimed for the instrument consist in—

1. The simplification of the mechanism, its lightness, its never failing to cut, and its being easily kept in order.

2. Its enabling the operator to remove the tonsil with one hand only.

3. The fact that when the instrument is in the grasp of the two forefingers and thumb, it may be applied to the tonsil (either right or left), and while the knife is thrust forward by the thumb, the double fork (as seen in the wood-cut) is brought into action, seizing and elevating the tonsil sufficiently for its removal.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 28, 1873.

EDITORIAL.

CHEAP!

"JOHN," said in our hearing an acquaintance old in experience and rich in this world's goods, when speaking to a young nephew about a certain scheme which it was thought would redound to the credit of those identified with it,—"John, never thee mind the credit; thee look after the cash." Remembering this incident, we have been tempted to pry into the cash account of the Philadelphia Hospital, and desire has been warmed into action by sundry eulogiums we have recently heard pronounced upon the economy with which the institution is managed. As a student and physician, not rarely have we trod its halls; and, calling to mind its stairs half worn away by the tread of misery, its floors whose gaping cracks and seams offer inviting resting-places for contagion, its wards whose naked dreariness speaks of the work-house, we are ready to acknowledge that, if economy and poverty are synonyms, Philadelphia Hospital has the most economical appearance it has ever been our lot to witness in an institution of such character.

We have gone further, and, examining its financial statistics, found that the average cost of patients per week was, in 1869, $2.46; 1870, $2.49; 1871, $2.65; 1872, $2.53.

In this are included food, clothing, light, heat, nursing, medical attendance, a priest to shrive, a coffin to lie in, a grave to rest in,—all for $2.50 a week! Certainly this is cheap. Pleasant—is it not?—for the tax-payer.

No one who has ever been in the Pennsylvania Hospital at meal-time would complain that the patients there are over-fed. No one who has personal knowledge of its honored steward would assert that he is extravagant in ideas, or not well skilled in practical economics. Yet there the average cost of patients is a little under $7.50 a week. Seven dollars and a half versus two dollars and a half! Certainly there is a difference,—a difference which becomes more marked when it is remembered that in the Pennsylvania Hospital the patients wear their own clothes, but that in the Philadelphia Hospital they are furnished with others.

Taking the year 1869, because at present writing its report is the only one at hand, we find that the average cost of food in the Philadelphia Hospital was per week $1.40; twenty-one meals, 6¾ cents a meal, including beef-essence, milk, eggs, and all other forms of extra diet. Six and three-quarter cents a meal for the patient consumed with fever! Six and three-quarter cents for the sewing-girl exhausted with toil and daily struggling! Six and three-quarter cents for the debauchee broken down with excesses! Six and three-quarter cents for the frame wasted with the hectic of phthisis! Six and three-quarter cents for the men and women pouring out their life from chronic abscesses, struggling to pass a certain point as a ship in a storm upon a lee shore struggles to round a promontory beyond which lies smooth water! One fi'penny bit for life! Certainly this is cheap. Pleasant—is it not?—for the tax-payer.

Man of wealth, dining sumptuously every day, wasting your strength with the rich viands of luxury, twenty cents per day is what the city of Philadelphia allows for the sustenance of the sick and dying in the only hospital *which is freely open to receive all those who, mayhap in the midst of honest toil, are stricken with disease, and who, being dependent upon their daily work, are, when disabled, nothing but paupers in the eyes of this Commonwealth.*

In our obtuseness it has occurred to us, however, that may-be the economy is more apparent than real. We have reasoned in this way. If a rheumatic patient takes cold and suffers relapse from insufficient clothing, what difference does it make if you have saved half a dollar by keeping him without a flannel shirt? If a chronic diarrhœa becomes incurable from want of suitable diet, and the patient remains a permanent inmate, where is the economy? If a fever case drags its convalescence for want of proper nourish-

ment, how is there a saving for the tax-payer? In a word, as no man in his senses, imbued with any regard for the truth, would assert that hospital patients can be properly fed in Philadelphia on six and three-quarter cents a meal, to protract convalescence—to convert an acute case into a chronic one by improper nourishment—seems to us no economy.

SINCE the above editorial was in type, we have heard some complaint against the one on the Philadelphia Hospital which appeared in our issue of June 14. Especially have we been asked, What are you driving at? Why not state plainly what you mean? Well, we did try to speak plainly, as far as we went. We did try to say forcibly that the practical daily government of the hospital is not centred, as it should be, in one person, but is left to a number of subordinate officers, who from the very nature of the case are incapable of managing the institution, and who, in practice, are not even bound by the printed rules of the house.

Some have construed our editorial—unjustly, we think—as bearing hardly upon the *present* resident physicians. Any such intention we entirely disclaim. According to the unanimous voices of their superiors, they are able, faithful, and self-sacrificing. We did mean to assert that, in such a staff, annually chosen for a term of months, there must be, from time to time, all sorts of characters; that all of the staff are, of necessity, inexperienced; and, further, that the printed rules for their government are, as they long have been, practically a dead letter.

The space allotted to editorials in our journal is too small for us to display in a single number the many shortcomings of the Philadelphia Hospital. This can only be done by a series of articles. We can, however, in a few lines, make definite charges, each capable of forming the basis of an editorial of some length. Let us at present arrange a few new ones, as follows:

1. That the sick poor are degraded morally by being regarded as paupers,—uniformed as such, and by being forced into the closest association with paupers.

2. That the food of the Philadelphia Hospital is not what it ought to be for hospital patients. This we have tried to show in to-day's issue.

3. That the nursing and attendance, although improved of late, are insufficient.

4. That, whilst some of the wards are comparatively airy, others are so unfit for their purposes that no language seems too strong to denounce them in.

5. That in winter the wards are frightfully overcrowded,—not merely the regular beds being filled, but numbers of the patients being forced to lie upon the floor.

IN calling attention to long-standing abuses, it is impossible to avoid hurting the *amour-propre* of some one. In the present instance we desire to state plainly that the fault does not lie with the governing or medical board, or even indeed with the City Councils, but rather depends upon the erroneous idea which underlies the whole matter, that the city hospital is an institution for paupers, to form a part of an almshouse and to be governed as a workhouse.

The present system has been handed down through successive generations of guardians; each man when first elected perhaps resisting the current, but soon yielding to the general opinion that the place is good enough for paupers, and finally settling into the belief that the Philadelphia Hospital is a great and blessed charity.

So far as they have known, we believe that the hospital committee have tried to do their duty: the executive of an improper organization, they are powerless to overcome the faults inherent to the system. As constituted to-day, the committee probably has more knowledge of the wants of a hospital and a clearer appreciation of the existing evils than ever before. Their honesty of purpose is beyond dispute. The attention to their duties given by all of the members is great, and the sacrifice of time and labor on the part of some of them merits the highest praise. Indeed, our utter despair for the future of Philadelphia Hospital, as now constituted, rests largely upon the conviction that although the committee fails to accomplish anything of moment, its *personnel* is of such high character that any improvement of it is most improbable.

We know that various attempts at reform have been made by the governing committee and by the medical staff during the last few years; but we know also that the improvement really achieved amounts to very little, and are sure that the only solid basis for improvement in this case is *revolution*,—a complete separation of the hospital from the almshouse; a recognition of the cardinal fact that a man disabled by sickness, even if brought upon him by vice, is yet a man to be nursed, attended, cured, and to be restored as a useful citizen to the state.

AT the risk of wearying our readers, we reiterate that the articles on the Philadelphia Hospital which have appeared in our columns have been written solely and purely to call, if possible, public attention to a matter which most pressingly needs it. We have no fault to find with the governing board or officers of the institution. With the amount of money placed at their disposal, with the system which has prevailed since time immemorial, we believe the best results that can be are achieved by the Board of Guardians. For the credit of our city abroad, for the sake of the suffering poor, in the name of Christian charity, we do and shall continue to plead for a complete change in the system, for the organization of a disciplined, creditable hospital,—separate and distinct from the almshouse,—a house of refuge, whose wards shall indeed be temples of blessing to the sick and the weary.

To the present Board of Guardians above all do we appeal that they aid us in laying the whole matter before the community, and in informing public opinion, that it may justify City Councils in making the increased appropriations without which no improvement of moment is possible.

We do not think that we have in any wise put the truth in too strong a light; we do not think, indeed, that we have laid bare all the evil: if, however, in the opinion of any one having knowledge, one unjustifiable word has been said, our columns are open for communications upon the subject.

THE Committee on Reform and Retrenchment reported to the City Council, on Thursday, June 19, a bill for the sale of the present Almshouse farm, and removal of the Almshouse to a position near the present House of Correction. The bill was postponed by Councils until Thursday the 26th, and, as the meeting of that date is the last of the season, and the matter is too important for hasty action, probably nothing will be done until fall. Any discussion of the bill at this time would, therefore, be premature; and we content ourselves with saying that, if proper measures be adopted, in this movement will be found the cure for the troubles we have spoken of.

THE VACANCY AT THE JEFFERSON COLLEGE.

WITH a smile that is childlike and bland, our friend the editor of the *Medical and Surgical Reporter* rises (issue of June 21) to explain to the admiring Board of Trustees in the Jefferson College their duty in regard to the vacancy in the chair of anatomy. With the sweep of the well-used and well-abused weapon, the cry of nepotism, he chops off the head of one of the prominent candidates; with faint praise he lays low another; with absolute ignoring he covers the third; and then in the strong light of his favor he holds forth his candidate as the man among men.

We have always had a respect for clannishness,—for the loyalty to kindred which prompts a man to aid those in whose veins flows blood like unto his own. But when the editor of a medical journal, in his public capacity, allows himself to carry the principle into his editorial columns, or even to appear to do so, he certainly throws himself open to censure, and in most cases damages the candidate whom he would help.

Except in very rare instances, a medical journal has, we hold, no business to interfere in a canvass of this kind, much less to insinuate that nepotism may influence the appointing board.

If any one candidate stands out pre-eminently above the rest, if the unanimous voice of the profession be in favor of one man, it may be the duty of a journal to speak in behalf of its constituents; but on an occasion like the present, when the alumni and the faculty of the college are divided in their choice, when the availability of the various candidates is such that it is a matter of individual opinion as to who is the best man, any journal that attempts to direct the various currents into one channel simply injures its own influence, if it possess any.

In conclusion, we wish to say one word in regard to "nepotism,"—a word which we would leave unspoken did we not know that ere it reaches the reader's eye the election will have been decided. If a man build up a business in ordinary life, it is the universal and just custom, when age or sickness overtakes him, to hand it over to his children. A position in a medical school differs, it is true, from a private business, but not so absolutely as some contend. The prosperity of almost every school rests upon the reputation and exertion of at most two or three professors; and we believe it to be nothing but common justice that when this has been the case such professors should have a claim upon the school for their children,—a claim which should not be paramount, but which should not be lost sight of; a claim which should not interfere with the election of a man superior to the son of a professor, but which should always give to that son the advantage, provided he prove himself the equal of his competitor.

Not being in any sense on the inside of the canvass, we have not the slightest idea who will be elected this afternoon; but we shall keep back the issue of our journal so as to inform our readers. Editorially, we are for the best man; but we consider it the duty of the trustees of the Jefferson College—not ours—to decide this knotty question. As to probabilities,—like the Irishman at the "Limerick races,"—"two to one that the foremost horse wins."

CORRESPONDENCE.

THE following letter was handed us by a prominent practitioner, to whom it was sent by one of his patients. We would call especial attention to it, because we are well convinced, from some experience, of the truth of much that is said in it:

DEAR DOCTOR,—Thanks to a kind Providence, I feel myself now at last so well that I am able to answer some of your questions. I mean besides to give you the conclusions I have come to after being an inmate of three asylums, and I venture on this because I was so long near well as to have for many months as good power to see what went on, and to judge of things, as any one not a doctor. I meant at first to speak out about each asylum, but in all of them I had great kindness shown me, and I have been told that if I name them I shall do them harm, and keep people from being sent to them, to the loss of both sides. If what I say here is unreasonable or foolish, do not print it. If it is not, I would like done with it whatever can be for best to such as are the miserable sufferers I have been. I have talked with many insane people, and found that they, many of them, have physical pains or annoyance which are not much looked after in asylums, and I am sure that in two of those where I went I never had such a thorough overhauling of my chest, and heart, and stomach, and head, as my outside doctors have given me. I was surprised to find lately that examination of urine is necessary, and know that no one ever in these places did look at mine. Asylum doctors cannot be much blamed; because where I have been there was always too few doctors, and the youngest ones were always going and coming. Even if a doctor lives among crazy people constantly he must tire of their complaints which so many are false, and therefore must get heedless of real ones. My remedy would be to get one or two good doctors outside to come once a week and see cases, and perhaps they would be fresher to see into the body ailments.

I saw in asylums many persons who were harmless, and who I guess would be more happy at home, and sometimes were really incurable. I suppose that if the cause of a man's madness was in what surrounded him at home he ought to be away from it; but if this is not so, why must he be in an asylum unless he is so handled by his disease as to be dangerous?

It may seem a little thing, but I used to have at home a great variety of eating, and in one asylum, though food was plenty, it was coarser than people well-off at home are accustomed to, and it was not various. Perhaps if the visiting doctors could come in at meals now and then it would be a good thing. As to managers, they come out on set days, and know very little of all that goes on.

The worst complaint I can make is about what kept back my recovery a long while. I saw in asylums many people who were just so far well that the monotony of their lives was dreadful. You can't amuse a man all the time; and if a man has been a hard worker, as he gets better he ought, as I think, to be put to work. I would say, do so much labor of one kind or another each day, and if you do it you will have certain privileges, better diet, or moderate use of tobacco, if wanted, or a ride outside.

I was a long while just so that if I had had a reason to work I would have gladly done it, in a garden or field. Cannot this be carried on as a system in some asylum? No one but a nearly sane man knows what it is to have to walk about with more crazy people all around, and to have just games and the like to fill his day up. My own feelings would make me think that good hard labor would help some people as they get better.

I am sensitive about my name being known, but I should not be sorry for you to publish this if it will do any one good.

Yours, truly and respectfully.

——— ———.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, May 28, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

BY request of the Common Council, the Society met to discuss the propriety of using the waters of the Hudson for city purposes.

The PRESIDENT opened the meeting by stating the subject for discussion, and remarked that it was one of grave importance to all. They had met, not to compare the water of the Hudson with other sources, but to decide as to the fitness of the river-water for culinary and drinking purposes.

Dr. LEVI MOORE remarked as follows: "Mr. President, the question before this Society is one of great importance. We are asked as physicians if the water of the Hudson River is good in a sanitarian sense. The hygienic aspect is the only one for us to consider. I trust that whatever action we shall take will be prompted by a sincere desire to secure to the public the greatest possible immunity from the germs of enteric and other diseases which we are so often able to trace to the use of impure, tainted, or sewage water. Whatever experts may say in commendation of sewage water,

even when largely diluted with purer water and taken from a rapidly moving current, although it may be clear and sparkling and possess no unpleasant taste or smell, yet the common instincts of our nature repel it as unfit for domestic use.

"I need not bring to the attention of this Society instances where typhoid fever, cholera, dysentery, and other diseases have been clearly traced to the use of impure or sewage water. These cases have been too numerous and too well authenticated to be doubted. The germs of disease are often too minute, too subtle, to be weighed in the chemist's balance, or to be detected by his most careful analyses. Because he cannot detect any death-dealing poison in the limpid fluid, does he therefore presume to say that there is none, and that the water therefore is wholesome and good? Because the continued use of small doses of an active poison does not kill at once, is it any the less a poison?

"My own conviction is that the water of the Hudson River is entirely unfit for domestic use, receiving as it does the sewage of our city, and, within ten miles to the north of us, the sewage of the cities of Troy and Cohoes, and the village of West Troy. All this sewage, together with that from the villages on the Upper Hudson and Mohawk, flows past our city and mingles with the sewage which is here poured into the river. I see in the not distant future a dense population, double, quadruple, the present number, in the manufacturing city of Troy and in the young city of Cohoes, with its matchless water-power. West Troy will have its population largely increased, and the beautiful hill-sides between that point and this city are yet, I believe, to be thickly populated. All this drainage will flow into the Hudson River only a few miles above us, tainting its waters and rendering them each year more and more unfit for domestic use. It is a notorious fact that even now the drainage from a large and rapidly-increasing population flows into our present source of supply. This should be remedied at the earliest possible moment. The very fact that it has continued till it has become so serious a matter shows culpable carelessness somewhere. This Society should take such action as the importance of the subject demands."

Dr. W. G. TUCKER read a paper on the analysis of river-water. "This," he said, "contains organic matter generally in much greater proportion than spring-water does, because of the surface-drainage passing directly into rivers. Inorganic matters which they contain are of little moment except as they affect the hardness of the waters. Organic matters, from various sources, are diffused through the water, and, being brought into contact with the oxygen contained therein, gradually change into carbonic acid, ammonia, nitrates, and nitrites. Thus the oxygen in water plays an important part in the purification of water. This is especially important where rivers receive, in addition to surface-drainage, a large amount of sewage from towns, and in hot weather, especially, this natural process of purification is inadequate to prevent a putrefactive change.

"The wholesomeness of water appears to be intimately connected with its state of aeration, as the proportion of oxygen is liable to be lessened by the decomposition of organic constituents.

"Thames water was examined at various points by Miller, and the proportion of oxygen contained in it ten miles above London was normal; three and three-quarter miles below it was very greatly diminished, and fifteen miles below it was very much restored to its natural condition, though not entirely. This was due to the pouring into it of organic matter from the city, to the destruction of which oxygen was necessary. These examinations show that water is wholesome much in proportion to its degree of aeration.

"Hudson River water was examined by Dr. Tucker by what is known as the permanganate test, which is based on the oxidation of organic matters, this being preferred as the most delicate. During October and November last he made several examinations, with the result that about four-tenths of a grain was liberated to oxidize the organic matter in one gallon; city water examined at the same time required one-eighth of a grain per gallon. Early in February, river-water required sixteen one-hundredths of a grain, city water seven one-hundredths; in April, thirty-three one-hundredths of a grain was required for river-water; city water was not tested at this time.

"Prof. Nichols, of Troy, examined, by the same test, water from the river above Waterford bridge, and that in the Troy reservoir, and found a proportion in favor of the latter of 1 to 4. Other properties of the river-water are a yellowish-brown or green color; it is turbid, with considerable sediment on standing; it contains ammonia in traces; its hardness is 3.9 degrees, city water averaging 5 degrees. Prof. Maynard, of Troy, found 4.94 grains of solid matter per gallon, 1.08 grains being organic; and he expresses the opinion that the waters of rivers receiving sewage are unfit for domestic use.

"The examination of water made by Prof. Chandler," Dr. TUCKER said, "does not fairly represent the character of the water, because the sample was taken from under the ice in the latter part of the winter, when, being at a low temperature, it would hold less in solution than during the summer. There is also at that season much less opportunity for foreign matters to get into the water. Prof. Chandler's report gave, however, at this season, seven-tenths of a grain per gallon of organic matter."

Dr. TUCKER believed that taking river-water for a city supply involved a great risk. A single analysis is not sufficient to determine the purity of the water, but it must be examined at different seasons, states of the weather, and stages of the river. The examinations already made do not warrant its use.

Mr. G. MICHAELIS, by a vote of invitation, remarked as follows:

"Gentlemen:—It is not the place here, to give you a review of the chemical and mechanical properties of the water; it is another point altogether which we have to take in consideration, and that is the purity or impurity of it.

"All waters, river-water as well as well-water, are powerful solvents of the ingredients of the soil, and contain therefore a variable quantity of the salts which are frequently found in it. They are principally chloride of sodium, sulphate of lime, magnesia, salts, and so forth, which give the water, especially when it contains carbonic acid, a refreshing taste, and there is no doubt that they have a healthy influence on the human body.

"But all waters, no matter whether river- or well-water, contain more or less organic matter, and it is supposed, to a certain point certified, that the latter is obnoxious to the human body, and produces sickness. The sources wherefrom the organic matter in rivers come are well known; they are, principally, the sewage and manure of the towns and villages through which they flow, consisting of almost everything, urine, fæces, dead animals, and the decay of the plants of the stream. A water thus impregnated is undoubtedly not very healthy.

"On the other hand, speaking of well-water, we must state that wells in cities are very quickly spoiled by infiltration of manure, and thus become bad.

"I made an experiment which showed this in the spring of 1866, when cholera was imported from Russia to Germany. This raised general alarm throughout the country, and more so since some prominent physicians

supposed that the ground-water had something to do with the spreading of the disease. I was at that time in Posen, a city of about 65,000 inhabitants, in the chemical laboratory of Dr. Mankiwich, occupied as his assistant. This gentleman received an order from the city authorities to analyze the water of the city wells. A thorough investigation proved that nearly one-third were in a bad condition and entirely unfit for use, but some of the wells, even those with a large amount of organic matter, appeared clear to the eye, while others had a good taste and very little smell. An analysis made of the water of the river Warthe proved that it was in at least as good a state as the wells.

"We must understand that there are two distinctly different organic matters in the water: such are those dissolved in the water and those only mechanically suspended in it. The mechanically suspended matter can be easily eliminated by a careful filtration, as filtering through gravel or sand and charcoal, but the greater part of organic matter is dissolved in the water and cannot be separated by mere filtration. It is beyond doubt that the dissolved organic matter is the source of the bad odor and the yellow, brownish color. Pure water is colorless. Now, the question is, whether there is a possibility of eliminating the dissolved organic matter or not. This question was satisfactorily answered by Prof. Medlock. This gentleman was requested in the year 1856 by the Amsterdam Water Company in Holland to analyze their water and to find the cause of the bad smell and fishy taste. (I wish you to understand that the water in Amsterdam is let through iron pipes.) Medlock received five samples of water for analysis, four of them from pipes in the city, and one before the water entered the reservoir of the company.

"In the water from the works before it came in contact with the iron reservoir and pipes, this chemist found 0.95 grains of iron, while in the other samples the iron was reduced to an unweighable trace: thus, instead of taking up iron from the service-pipes, it was not alone diminished, but even all precipitated. Notwithstanding the almost entire precipitation of the iron actually in solution in the water which had passed the iron pipes, it formed an objectionable red deposit on standing, while the water from the works before entering the pipes, holding in solution nearly one-half grain of iron per gallon, formed no deposit. He examined the deposit chemically and microscopically, with the following result: On ignition the precipitate charred and was almost entirely consumed, showing that it consisted of organic matter; under the microscope the deposit was seen to consist of plants in various stages of decay; many of the fibres had even retained a perfectly organized structure. He remembered the important fact established by Schönbein, that copper and platinum can convert ammonia into nitrous acid, and he found that iron also transforms ammonia into nitrous acid, and by further investigation he found that strips of sheet iron placed in water containing ammonia or organic matter capable of yielding it act almost as quickly and well as the metal in a finely divided state.

"Now he made different analyses with water brought in contact with iron, and water in no contact with iron, and the result was, that while the water which was not brought in contact with iron contained 2.10 organic matter and 0.96 iron, the other contained only an unweighable trace of both, which showed plainly that the organic matter contained in the water was either decomposed or thrown down (rendered insoluble by contact with iron); and actually this water when filtered was clear, of good taste, had no smell, and was free from organic matter.

"All organic matter either contains nitrogen or is non-nitrogenous. The latter consists almost always of carbon, oxygen, and hydrogen, and is very quickly, as soon as it is no more under the vital influence, converted into carbonic acid and water. The nitrogenous matter is mostly of animal origin, and consists of nitrogen, oxygen, hydrogen, and very often sulphur and phosphorus, and is dissolved or suspended in water, very rapidly decomposed into gases very offensive to taste and smell, and undoubtedly very obnoxious. But all these are immediately destroyed by the presence of nitrous acid. Medlock proved, as before stated, by a series of subsequent analyses, that iron produces nitrous acid by its action on the nitrogenous organic matter, which is the most destructive power nature has. Muspratt calls it 'Nature's scavenger.' This chemist found as a general result that by allowing water to be in contact with a large surface of iron, in about forty-eight hours every trace of organic matter was either destroyed or rendered insoluble, in which state it could be purified effectually by filtration.

"I did the same way with our Hudson River water, and obtained the same results. After subjecting the most filthy water to the influence of iron sheets for forty-eight hours, I found that it was almost entirely freed of all organic matter.

"I submit to the honorable Society some samples of Hudson water which I treated in a similar manner; and it can be easily seen that the iron sheets have had some influence on it: there is a decided deposit.

[Specimens of water treated with iron sheets, which appeared to be perfectly pure, were exhibited.]

"It would be perhaps of some value if similar researches should be made, and, in case the results should be favorable, it would not make any difference wherefrom we receive the water, as long as we are able to purify it in such a manner as to render it a wholesome beverage for the community.

"The experiment shows the existence of organic matter in the river-water."

Dr. SABIN said that analyses which had been presented showed the water opposite the city not sufficiently pure for use: he thought the best plan was to take water from the river just below the State dam above Cohoes and Green Island. At this point it is purified by running over the dam. He proposed that a large well be sunk at this point; that it be stoned up at the bottom with loose stone within ten feet of the top, the rest being cemented and built above high-water mark. By this means water will be taken from the bottom of the river, and also filtered, while the top floats off.

Dr. WILLIAM HAILES spoke of experiments which had been made to purify water, showing it to be a fallacy that water is purified by flowing over a dam. Pure water mixed with fecal matter in vessels, and poured day after day over a rough board, allowing it thereby to be most intimately mixed with air, at the end of two weeks was still found impure. It is also a fallacy that digging wells and so filtering purifies water, as it has been proved that filtering does not purify it. The germs of disease are not removed by it. He thought that river-water here, and even at the State dam, is unfit for use.

Dr. CROTHERS followed in an admirable address, for which we have not room.

Dr. JAMES S. BAILEY remarked that he had been much interested in what had been said, especially in the careful analyses of the chemists; but it had occurred to him that they might be more technical than practical. The air we breathe might, by analysis, prove to contain deleterious elements, but still we live and apparently enjoy health. So with river-water; it undoubtedly contains organic matter, but when taken into the stomach does not prove deleterious to animal economy. He had known persons—in fact, whole families—to drink river-water constantly with impunity, and from South-

ern waters, which were known to be more deeply impregnated with earth and vegetable matter than the water of the Hudson. He had known families to use water from stagnant pools covered with green scum, by brushing this aside, and the water, when used, did not produce unhappy results. There are processes in nature —chemical processes, really—by which water is purified, which is exemplified in the commingling of the waters of the Mississippi with those of the Ohio at Cairo, one coming from the limestone country, and the other laden with earthy matter, which when united had the desired effect of producing a chemical change, in fact, a filtering process; and it is a fact well known by river-men that water in this vicinity is unusually pure and wholesome.

The city of New Orleans is supplied with river-water, and it is known to be one of the healthiest cities in the Union, aside from epidemic influences; and by way of illustrating the turbid character of the water he would say that when last passing through that city he wished to enjoy the refreshing influence of a bath. After finishing, he had a desire to see how much impurity it contained, and was surprised to find a deposit of two inches of mud in the tub after the water was drawn off. Alum was used there to deposit the sediment.

Dr. CRAIG said the Hudson River water had been used for very many years for drinking purposes; ships going to sea came up into the Hudson River and took their supply. He said the Hudson River contains a volume of water four times as large as the river Thames, and the city of London is supplied from the latter. He thought the Society should not be hasty in its judgment, or too ready to condemn the source of supply.

Dr. DAVIS remarked, "The statement made here this evening that river-water has been used with impunity, and is therefore innoxious and wholesome, reminds me of accounts given by travellers of some barbarous tribes who habitually eat their food in the most offensive state of putrefaction and decay. Civilization, with its overtasked brain and nervous system, can never withstand such vile and unwholesome food. No more can we long endure the baneful influence of river-water filled with putrescent vegetable and animal substances drained from an extensive region of country, and to which is added the sewage of cities holding in solution vital and putrefactive animal poisons, without subjecting ourselves to the natural and inevitable consequences of taking into our systems those active morbific agents which have ever proved most destructive to humanity. The rivers are the common receptacle of every unclean thing; and when the shores are covered with the dense population of large towns and cities, the sewage of every dwelling, prison, hospital, and sick-room is mingled in the general mass of its impure waters, containing epidemic, contagious, and infectious elements. Chemistry has its range and its limits, and has never been able to detect those attenuated and subtle principles that produce the desolating ravages of cholera, cerebro-spinal meningitis, smallpox, fevers, and numerous other diseases; and yet than their existence no truth in the whole history of medicine is better established.

"I hope this Society will place upon it their disapprobation, and will express with emphasis their answer, No."

On motion, it was decided to continue the discussion at the semi-annual meeting to be held on the 10th of June.

THE PULSE OF VARIOUS ANIMALS.—Vatel, in his "Veterinary Pathology," gives our domestic animals the following pulse: Horse, from 32 to 38 pulsations per minute; ox or cow, 25 to 42; ass, 48 to 54; sheep, 70 to 79; dog, 90 to 100; cat, 110 to 120; rabbit, 120; Guinea-pig, 140; duck, 135; common fowl, 140.

REVIEWS AND BOOK NOTICES.

A GUIDE TO URINARY ANALYSIS, FOR THE USE OF PHYSICIANS AND STUDENTS. By HENRY G. PIFFORD, A.M., M.D., Physician to the Charity Hospital, to the New Dispensary for Diseases of the Skin, etc., etc. 8vo, pp. 88. New York, William Wood & Co., 1873.

We are glad to welcome this manual with the same hope expressed by the author in his preface, "that the simple and easy manipulations described may encourage the more frequent and more thorough investigation of the urinary secretion," although it contains little that is not elsewhere published. We have good reason to know that the accurate investigations implied in a knowledge of these manipulations are rather distasteful than otherwise to the average American student; for we have attempted to teach them in a large medical school, in which, however, attendance on the course was not compulsory to the class, and have sometimes found ourselves teaching to almost empty benches. Not until by preliminary examinations we sift the wheat from the chaff will the average medical student seek any further instruction than such as will aid him in his final examination.

The book is convenient in form, and the processes described are in the main reliable. We cannot believe, though, that the author has had much experience in testing for the bile-acids, or he would not have been so brief in his treatment of this subject. It is true he says that *sometimes* the bile-acids may be detected in urine by Pettenkofer's test directly applied to the suspected urine. In many trials we have *never* been able to prove the presence of the bile-acids in urine by the direct application of Pettenkofer's test, *even when we have added human bile* to the urine previous to testing. The bile-acids must first be *extracted* and obtained in colorless solution, either by evaporating to dryness, extracting with absolute alcohol, precipitating with ether, redissolving in distilled water and decolorizing with animal charcoal, or by the still more accurate methods of Hoppe-Seyler and Gorup-Besanez, before Pettenkofer's test can be applied.

Containing seven chapters, the first is the introduction, the second describes *apparatus*, the third *reagents* and *standard solutions*, the fourth *color, reaction, specific gravity*, and *estimation of solids*, the fifth *estimation of normal constituents*, urea, uric acid, etc.; sixth, *abnormal constituents;* seventh, the detection of *medicinal and other substances* in urine, including iron, lead, and mercury.

We would have confined ourselves to the metric system of weights and measures; for it is only by persistently adhering to it, and as persistently ignoring the English system, that scientific men can expect to secure its ultimate adoption. The book should be in the hands of every American practitioner and student.

THE COMPARATIVE MERITS OF CRANIOTOMY AND THE CÆSARIAN SECTION IN SMALL PELVES. By J. S. PARRY.

This is a reprint of Dr. Parry's paper read before the Philadelphia Obstetrical Society, and published in the *American Journal of Obstetrics* for February, 1873. A more clear, searching, and practical paper has seldom been read before that body. Its text—a case of delivery by craniotomy through a pelvis of one and a half inches antero-posterior diameter, at the Philadelphia Hospital, by the author—is told in forcible and graphic language, and followed up by arguments and statistics which serve conclusively to prove the vast superiority of the Cæsarian section in pelves below two and a half inches, and still more, if admitted, to make it obligatory on us, as an act of justice, to urge and insist upon

the performance of this operation in any such case which may fall into our hands.

Dr. Parry in his case found the cephalotribe of less use than its advocates would claim, and shows that, so far from obviating the necessity for Cæsarian section in many small pelves,—below two and a half inches antero-posterior diameter,—its usefulness diminishes as the antero-posterior diameter falls below this measurement. In this opinion he is supported in an article recently published by Dr. Munde, in the *American Journal of Obstetrics*, May, 1873, where, drawing his experience from the Vienna schools, Dr. Munde advocates the use of a modified and enlarged cranioclast on account of this very difficulty of applying the cephalotribe. Dr. Munde, however, admits that he is unacquainted with the cephalotribe of Braxton Hicks; though we think this detracts but little from the value of his observations.

We are convinced, however, that somewhat more than unanswerable argument will be required to make the Cæsarian section the universal resort. The battle of ovariotomy will have to be fought again on many fields before the ordinary practitioner will give up craniotomy and adopt an operation which, where unsuccessful, leaves so many external marks of violence; lacerations of the uterus, penetration of the peritoneum, bruises and sloughing from undue pressure and traction, are concealed; seldom do prying eyes see the hidden injury; and then the euphemism of child-bed fever or its synonymy comes and covers all from those idle eyes and equally idle tongues. It takes time as well as conviction to bring about radical reforms, in practice as in everything else.

GLEANINGS FROM OUR EXCHANGES.

Leprosy in the West Indies.—The subject of leprosy in the West Indies, though it has, perhaps, excited less attention than in the East, has always been looked upon with interest,—an interest which the reported cures of what was considered an incurable disease by Dr. Beauperthuy by no means served to lessen. Dr. Gavin Milroy, at the suggestion of the Royal College of Physicians, was sent out by the Colonial Government; and it is from his report, which now lies before us, that we extract the subject of this notice.

Dr. Milroy appears to have first of all visited British Guiana, near the capital of which is situated the principal leper-asylum in the colony. This at the time of visitation contained two hundred and six patients, in all stages of the malady. Most of these were colored, only one European being found among them, and his case was a doubtful one. The facts here collected tended to establish the belief, already generally entertained, that the disease is not transmissible by ordinary infection. Leprous patients continue to sleep with those who are sound, and even sexual intercourse seems to have no power of communicating the complaint. Hence the belief that it arises from causes dependent on climate or food; and the belief has long prevailed that the extensive use of poor food, especially salted fish, in these parts, had something to do with its continuance and spread.

The forms of leprosy seen were of the tuberculated and non-tuberculated kind. In some the anæsthesia had been so strongly marked as to occasion injury to the hands in cooking their victuals, no intelligence being conveyed of the sensation of over-heat even by the burned fingers. Most of the cases seen under the care of Dr. Beauperthuy were in the earlier stages; those well advanced were rejected as unfit for treatment. Dr. Milroy in his inquiries was strongly impressed with the view that in many respects leprosy and scrofula were closely allied, and this idea was strengthened on finding that in both Guiana and the West Indies leprosy went by the name of "king's evil,"—the old name for scrofula in this country. In both there is marked want of "power" or "tone," with feeble action of the heart, and an exsanguine condition of body. The ulcers, too, resemble those found in scrofulous subjects, and the well-known enlargement of the lymphatic glands in leprosy would probably be considered another point of resemblance. At the same time, the spread of scrofulous diseases in Demerara and the West Indies has recently been marked as decidedly on the increase.

Naturally, one of the most important inquiries we can make is as to the contagious character of the malady. On this point a sufficiently large accumulation of evidence has been made to enable us to come to some conclusion. It is true that in many parts of the West Indies and in Guiana the belief in the possibility of transmitting leprosy from one individual to another has been entertained; but a strict examination into circumstances tends clearly to the opposite belief. True, certain isolated cases have occurred where direct transmission may have been possible; but the mass of evidence undoubtedly goes to show that leprosy is not capable of communication even by sexual intercourse. It has been supposed that the inoculation of the blood of leprous patients might be capable of transmitting the malady; but in the case of a medical practitioner who cut his finger in an operation on a leprous subject, no such unfortunate result followed. He was unable to attend to his wound for a time, and, apparently as a consequence of this, erysipelas and destruction of the parts followed, so that the finger had to be removed; but no constitutional evil resulted.

But, if not contagious, how is the malady spread? On that, too, there seems a singular unanimity of opinion, if we may judge by Dr. Milroy's report. If not entirely caused, the malady is greatly favored, by the bad food and unhygienic condition of the lower orders, among whom the disease almost entirely prevails. In Demerara the aboriginal inhabitants, who lead healthier lives than the imported negroes, coolies, or the lower classes of the Creoles, do not suffer. Everywhere in these regions the diet of the poor seems to consist mainly of salted fish,—at no time a nutritious kind of food, and even then often inferior in quality. Sometimes a little salted beef or pork is added in the form of soup, but fresh meat is rarely, if ever, tasted. As the salt fish can only be looked upon in the light of a condiment to flavor the other constituents of diet, the negroes seem to favor the highest-flavored—*i.e.* the worst—varieties; though when they get the chance they are greedy after fresh meat. Invariably leprosy seems to be fostered in its onward progress by bad food, and retarded by better quality of diet. However, as matters now stand, there seems to be a difficulty in getting meat in the fresh condition. Sheep are imported into Guiana from New York or Boston, cattle from the Orinoco. Some are raised in Porto Rico, and many more might be so in Dominica. Meanwhile, the business seems neglected, and the poor suffer in consequence. For the same reason, milk is not readily attainable; and even the substitution of fresh fish for salt, though apparently easy, is not much carried out.

One great object of Dr. Milroy's mission was an inquiry into the possibility of curing this malady on the plan proposed by Dr. Beauperthuy. This gentleman founded his treatment essentially on the principles already laid down as to the causation of the disease. The first thing to be done was to improve the dietary. Whenever the food has been improved, the lepers have improved also, and this, too, without any other medicines being employed. For the means of making such an improvement Dr. Beauperthuy stipulated when he took charge of the trial made in Guiana. Internally he gave

one-eighth of a grain of corrosive sublimate twice a day, sometimes with a dose of carbonate of soda, and this was continued until the mercury began to show its constitutional effects, when it was replaced by quinine, and later by iodide of potassium. Unfortunately, Dr. Beauperthuy did not live to complete his work, which he seems always to have considered experimental, and not final, so that even his final conclusions were of necessity imperfect. Locally he employed almost solely cashew-nut oil, which was applied to the tubercles or anæsthetic spots. This oil is a powerful counter-irritant, and may give sharp pain. By it the epidermis is removed, and to the raw surface strong lime-juice is applied. This plan of treatment, according to Dr. Milroy, is decidedly encouraging. By it tubercles are removed and anæsthetic spots rendered sensitive. Dr. Milroy, however, decidedly objects to the too prolonged use of mercury internally. Dr. Beauperthuy is no more; but his good deeds live after him, and we cordially endorse Dr. Milroy's warm praise of a man who devoted so much pains to assist a class so proverbially outcast as the leprous.

Dr. Milroy's report also contains some information as to the peculiar malady called the "Yaws," which, however, space forbids us in the mean time to reproduce.—*Medical Times and Gazette*, May 31.

MISCELLANY.

As we go to press, we learn that the trustees of the Jefferson College failed to elect a successor to Professor Pancoast. It is said that there were eighteen ballots, on the first of which Dr. William Pancoast received five votes, thirteen trustees being present. Subsequently Dr. William W. Keen obtained six votes. The closing ballot is said to have stood—Dr. Pancoast three votes, Dr. William S. Forbes six votes, Dr. Keen four votes. During the balloting Drs. Brinton and Hewson received some votes. The matter stands over until October. Professor Pancoast, we believe, is to be asked to lecture next winter.

The terrible physical sufferings endured by the Parisians and shared by many unfortunate foreigners who happened to be within the iron belt during the siege of the Gay City by the Teutonic forces, have become a matter of history. Not so the mental horror which must since have preyed upon many a sensitive organization on perusing the recent account of the trial, in Paris, of a wretch for selling pies made of human flesh during the bombardment. Meat pies, even in times of peace and plenty, amidst a great centre of population, are at once a mysterious effort of perverted ingenuity, and a hazardous investment; although the worst usually said of them may be that feline or canine choppings form their chief ingredients. There is something so utterly horrible in cannibalism, even although inadvertent, and in the deliberate calculation of this Parisian monster, that we do not wonder his unnatural crime, in exciting the utmost loathing throughout France, has enveloped the perpetrator with crushing punishment.—*Food Journal.*

Dr. David Page Smith, of Springfield, Mass., has been nominated to the corporation of Yale College for the professorship of the theory and practice of medicine, recently vacated by Professor Ives.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 17, 1873, TO JUNE 23, 1873, INCLUSIVE.

Magruder, D. L., Surgeon.—Granted leave of absence for sixty days, with permission to apply at Headquarters of the Army for an extension of thirty days. S. O. 55, Military Division of the Missouri, June 17, 1873.

Woodhull, Alfred A., Assistant-Surgeon.—Granted leave of absence for twenty days. S. O. 124, A. G. O., June 20, 1873.

Lippincott, H., Assistant-Surgeon.—Relieved from duty in Department of the South, and ordered to the Department of Arizona. S. O. 120, A. G. O., June 16, 1873.

Delany, A., Assistant-Surgeon.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 120, c. s., A. G. O.

Ewen, C., Assistant-Surgeon.—Assigned to duty at Baton Rouge, La. S. O. 95, Department of the Gulf, June 14, 1873.

SATURDAY, JULY 5, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF JAUNDICE, WITH REMARKS ON THE AVAILABILITY OF PETTENKOFER'S TEST FOR THE BILE-ACIDS.

Delivered May 14 and 21, 1873.

BY JAMES TYSON, M.D.,

One of the Physicians and Pathologist to the Philadelphia Hospital.

GENTLEMEN:—A mere superficial inspection of this patient will reveal the most salient symptom of the case,—a symptom which, like dropsy, from its conspicuousness has assumed in the eyes of the uneducated the dignity of a disease. But, although a mere symptom, it is true of it, as of dropsy, that there is sometimes advantage in its study in relation to the different diseases it attends, though in so doing we may appear to assign it an importance which does not strictly belong to it.

This patient, then, as you see, has jaundice, and it is a jaundice not to be mistaken. Not simply have the conjunctivæ a bright-yellow color, but even through the duskiness natural to him as a colored man do we observe the same yellow hue throughout his entire body. Let us read his history, and discover, if possible, the import of this jaundice:

B. B., colored, æt. 50, was admitted to the Philadelphia Hospital May 5, 1873. He is unmarried, temperate, but had syphilis thirty years ago. He is a ship's cook, and has spent most of his life at sea. His present illness began in December, 1872, with vomiting, chiefly of mucus, though after this had continued some time a small quantity of blood was also thrown up. The vomiting first occurred in the morning. At noon he went to his boarding-house feeling very ill, and at half-past six o'clock the same evening he was seized with diarrhœa. His own attention seems not to have been called to the jaundice until three weeks after his illness began.

These symptoms continued, and four days after the vomiting set in, he discharged by his mouth large quantities of pure blood, which coagulated on standing. He says he did not vomit it or cough it up; it simply ran from his mouth; and he thought the quantity a pint and a half.

The diarrhœa continued with interruptions until his admission to this hospital. On admission he was emaciated, his mind clear, his pulse 100, temperature 98°, his conjunctivæ and skin yellow, his tongue coated, and he had had twelve thin, watery stools the day before admission. When the evacuations became more consistent, they were observed to be dark gray in color,—potter's-clay-colored. His urine when viewed in bulk was reddish-yellow, but in thin layers bright yellow in hue; it contained no albumen. Gastric irritability had apparently ceased.

Physical exploration discovered but slight tenderness in the region of the liver. The anterior limits of the liver's dulness were not changed; the superior border being in the fifth interspace, the inferior at a line extending from the free border of the ribs to the median line. Laterally, however, the upper border of the liver was on a level with the sixth rib instead of the highest limit usually assigned in health,—the seventh interspace. The inferior lateral border was at its normal position,—the edge of the ribs. Posteriorly the superior border of the liver was noted at the eighth interspace; the inferior border appeared to be normally situated.

Let us now cull out the most striking symptoms of his history. They seem to be—1. The vomiting of mucus, and the diarrhœa. 2. The escape of blood from the mouth. 3. The jaundice. 4. The slight enlargement of the liver. 5. The presence of color-elements of bile in the urine. Note, also, the long duration of the jaundice, and the absence of pain, of marked tenderness, and of much enlargement of the liver.

In determining the disease of this patient, we naturally hover about jaundice as a centre. Now, what are the causes of jaundice? Unfortunately, they are numerous.

Not rarely jaundice is produced by emotion; it may also have its origin in certain general diseases, as yellow or remittent fever, and sometimes in typhus fever; or it may occur in the course of local disease of other organs, as in pneumonia,—and such pneumonias are generally fatal; but it is clear that we have here nothing to do with any such causes.

The most common causes of jaundice are those which, on the one hand, interfere with the secretion of bile, and thus cause its elements to be retained in the blood; or, on the other, prevent its removal from the gall-ducts, or its reservoir the gall-bladder, and thus permit a reabsorption of its elements by the blood. The result is the same,—a local deposition of bile-pigment in different parts of the body, and its appearance in the various secretions, particularly the urine. It is clear that such disease as causes deficient secretion, or, as it is technically called, *suppression*, must involve the parenchyma of the organ,—*i.e.*, its secreting structure; while *obstruction* will be produced by any affection involving the ducts or gall-bladder, or by any cause pressing upon them, whether it reside in the liver or an adjacent organ. Now, if it were possible, by the examination of any secretion, or otherwise, to settle the question whether the difficulty is one of *suppression* or of *obstruction*, it is equally clear that half of the difficulty in diagnosis would be overcome. Is this the case? Some, as Harley, do not hesitate to say so, while others, as Murchison, deny it. Let us see whether it is possible to determine the actual state of the question.

Harley declares that in cases of *obstruction* and *reabsorption* of bile the biliary acids are found in the urine, but that in cases of *suppression* the biliary acids are wanting in the urine. Now, theoretically this is what we should expect, on the supposition that the bile-acids are, as is generally believed, formed in the liver, since if secretion is interfered with no acids are produced; whereas if bile is secreted and subsequently reabsorbed the acids must be absorbed with it, and may then be thrown off by the kidneys.

Now, what are the means at our disposal for determining the presence of the elements of bile in the urine? To determine the presence of coloring-matter is easy, since, if simple inspection is not sufficient, we have only to place a drop of the urine upon a porcelain plate, and adjacent to it a drop of *nitroso-nitric* acid (the nitric acid is not nearly so satisfactory, especially if the quantity of biliary coloring-matter is small), and allow the two to approach, when, if the coloring-matter be present, a peculiar iridescence is noted, in which, if complete, there appears at first a *green*, which becomes more intense and then passes over into *blue*, *violet-red*, and finally *yellow* or *yellowish-green* again. All of these colors do not always appear, the violet and green being usually longest visible, and the first green the most indispensable. Another method of applying the same test consists in placing a small quantity of the acid (half an inch or an inch in depth) in the bottom of a test-tube, and allowing the urine gently to fall upon it from a pipette. The same play of colors, with more or less completeness, appears at the zone of contact. The reaction, you perceive, is unusually distinct in this case.

The determination of the bile-acids is, however, by no means so simple. Pettenkofer's test for them is familiar to most of you, but if you have no further knowledge of it than is contained in most text-books you will have concluded that its application is a very simple matter. The fact is that it is totally inapplicable to urine or indeed any organic fluid containing bile-acid even in considerable quantity. It is true that a watery solution of ox-bile or even of the inspissated ox-bile of the shops will give the beautiful cherry-red passing over into an opaque purple reaction of the bile-acids on the addition of a drop of syrup and subsequently sulphuric acid, drop by drop, until a bulk is added equal to that of the fluid to be tested. And the same result will sometimes follow the application of the test to urine to which either of these substances has been added. But if the test be applied to urine to which human bile has been added, or even to a watery solution of human bile, no reaction takes place except that due to the action of the acid upon the sugar. Nowhere are the cherry-red and purple colors seen. Evidently some cause interferes to mask the reaction. Nor have any of the modifications of Pettenkofer's recently announced as clinically available proved such in my hands, even where the biliary constituents have been added to urine, except where ox-bile has been used. The method I now exhibit to you is that of Strasburg, and recommended by Brunton in the new "Handbook for the Physiological Laboratory" by Burdon-Sanderson, Klein, and others. The urine to be tested is mixed with a dilute solution of cane sugar, and a piece of filtering-paper is moistened with the mixture and dried. The pieces of paper I now exhibit to you have been thus treated, some with normal urine, and some with the biliary urine from the patient before us. The next step consists in allowing a drop of pure concentrated acid to flow over the paper, when a beautiful purple "should be produced if the slightest trace of biliary acids be present." You observe that none of the papers—either those treated with normal or with biliary urine—exhibit this reaction. So that, if this test be relied on, no biliary acids are present in the urine of this patient. Yet when I tell you that I have thus treated filtering-paper with urine to which bile has been added, and have obtained no reaction with human bile, though I have obtained it with ox-bile, you will understand that this result can scarcely be relied upon. Can the question be settled in any way? I believe it can, but only by extracting and obtaining a solution of the bile-acids as free from color as possible. This may be done in the following manner. Six or eight ounces of the suspected urine are evaporated to dryness over a water-bath. The residue thus obtained is treated with an excess of absolute alcohol, filtered, and the filtrate treated with an excess of ether (twelve to twenty-four times its bulk), by which the bile-acids, if present, are precipitated. These are then removed by filtration and redissolved in distilled water. The solution is then decolorized by passing through animal charcoal, and Pettenkofer's test applied to the resulting colorless fluid. If the bile-acids are present, the cherry-red color will appear before the yellow discoloration due to the action of the sulphuric acid on the sugar.

A most frequent source of error is in the use of too much sugar. Thus, a drop or even two drops are often added of syrup containing so much sugar as to certainly mask human bile-acids if present in small quantity, although the reaction may obtain with the acids of ox-bile. A twenty per cent. solution of sugar should be used, *and of this only a single drop.* The officinal simple syrup is 250 per cent.,—that is, 2½ parts sugar to 1 water; whereas the proportion should be 1 sugar to 4 water. The method described, though somewhat tedious, is practicable even to the general practitioner, and when carefully practised may be regarded as reliable. For although other substances (olein, oleic acid, oil of turpentine, oil of caraway, and, according to Thudichum, also lithafellic acid, and cerebric acid "with rare intensity") have been found to respond similarly, yet these are not likely to be met with under the circumstances named. I might add also that Thudichum has discovered that there is a difference in the spectra of the colored test solutions, the biliary acids showing two bands, cerebric acid and vitellin only one. But these he tells us are difficult to observe, and require sunlight or the oxy-hydrogen light for their complete development.

Now, what are the facts in the case before us? I present you an uncolored solution obtained in the manner described from the urine of our patient. I now add a single drop of the very dilute solution of sugar, and now the sulphuric acid, drop by drop. A considerable bulk has been added, and you perceive no red color appears. Continuing the addition of acid, a yellow color begins to make its appearance. This is due to the decomposition of the sugar by the acid: were the quantity of sugar larger, the yellow would pass into brown.

But I have not relied upon this test alone. Desir-

ing to be absolutely certain, I have asked my friend Dr. Horace B. Hare to treat the urine by Hoppe-Seyler's process, acknowledged to be the most exact method. He has done so, and writes me that "*the urine contained no bile-acids.*"*

We have learned, then, that the bile-acids are *not* present in the patient's urine, and thence, following Harley, we would conclude that the parenchyma of the organ is involved. But the conclusions arrived at in a further careful study of the case are incompatible with this view, in this respect confirming the position taken by Murchison and others. I do not wish to be understood as denying that the bile-acids are ever found in the urine. On the other hand, Hoppe-Seyler has proven conclusively that they do occur; and I myself have found them by the process above described. I simply deny their necessary association with obstruction.

Let us determine the result to which such study leads us. What are the results of *physical exploration?* Palpation, you will notice, exhibits now absolutely no tenderness; and, although percussion shows the superior border of the liver to be somewhat higher than in health, laterally and posteriorly, yet the enlargement is not great, and there is none of that enormous extension of the liver below the edge of the ribs which is common to cancer of this organ. Further, neither percussion, nor palpation, nor, indeed, any of the symptoms, point to tumors of the stomach, pancreas, or other viscera which could produce obstruction of the gall-ducts. The absence of paroxysmal pain would also eliminate obstruction by a calculus. And yet that there is obstruction of some kind is evident from the hemorrhage, which, there is reason to believe, came from the stomach. Cirrhosis of the liver at that stage which would cause congestion and hemorrhage from the stomach by obstructing the hepatic circulation would be attended by diminished size of the organ and diminished area of dulness, and most likely, also, by ascites. These, however, are wanting.

What other symptoms remain to be considered? Only the irritable stomach, the vomiting, and the diarrhœa. But these, in connection with what has been said of the other symptoms, are by no means insignificant; indeed, in my belief they determine the diagnosis,—*inflammation of the biliary passages*, or "icterus catarrhalis with resulting obstruction." This condition is almost invariably preceded by these symptoms of gastro-intestinal catarrh, of which it is, indeed, an extension into the biliary passages. In connection with these, the very marked jaundice, the discoloration of the fæces, the slight tenderness, the small degree of enlargement, the absence of paroxysmal pain and of all symptoms of disease of adjacent organs, together with the absence of grave constitutional symptoms, all point to obstruction, most likely due to inflammation of the gall-ducts,—obstruction notwithstanding the absence of bile-acids from the urine. For, even if our own method be deemed insufficient, that of Hoppe-Seyler, followed by Dr. Hare, is accepted by the most critical as accurate and trustworthy.

The progress of the case, too, adds confirmation to this opinion. Six months have now elapsed since the symptoms set in; and, although the man was very ill on admission, he has greatly improved since under treatment, while the jaundice remains as marked as ever. One feature of the case, however, remains to be noted; and that is its duration. Biliary catarrh is generally a disease of short duration, not often continuing more than a month. But this is not invariable. Da Costa, in "Medical Diagnosis," third edition, p. 535, refers to the case of an adult male, aged 60, which occurred under his care in this hospital, and which terminated fatally. "At the autopsy the gall-bladder was found enormously distended, its coats thin, yet otherwise scarcely abnormal; but the common duct was obliterated by inflammation."

This suggests also the *prognosis*. And, although the disease generally terminates favorably, and our patient has improved under treatment, we fear from its long duration permanent occlusion and an ultimately fatal result. Indeed, the parallel to the case alluded to is a striking one, and I fear a similar termination.

What *treatment* is likely to avail us in these cases? Is it desirable to give remedies to promote the action of the liver, when there is already obstruction to the exit of the bile secreted? We believe not. On the other hand, we should expect by such treatment to increase the congestion, and thus hasten an unfavorable termination. And this is indeed the result of experience. We have already alluded to the frequent dependence of catarrh of the bile-ducts upon gastric and duodenal catarrh. The treatment of one would seem, therefore, to be the treatment of the other,—a conclusion also justified by experience. In the incipiency of the attack an emetic might be useful, which, in addition to relieving the stomach, might, by the jactitation induced, relieve the gall-ducts of a plug of mucus or force the bile past a swollen mucous membrane, and thus relieve the obstruction. When, however, there is permanent obstruction, as we fear here to have been induced, the emetic is of questionable propriety. Purgatives might be used for a similar purpose; but we believe the time for these, except to relieve constipation, is also past in this instance. The alkaline carbonates and the alkaline spring waters, as those of Karlsbad and Marienbad in Germany, and the Saratoga waters in this country, etc., useful in gastro-intestinal troubles, are indicated for the same reason in biliary catarrh. But, the acute symptoms having subsided, they cannot be expected to be of as much service in this case; whereas if they increase the secretion of bile, as is contended for by some,

* The following is Hoppe-Seyler's process, as furnished me by Dr. Hare: "Precipitate with subacetate of lead and ammonia; wash the precipitate somewhat with water; boil precipitate with alcohol, and filter hot. (The alcohol takes out the bile-acid salt of lead.) To this solution, after filtration, add enough solution of caustic soda to decompose all the bile-acid salt of lead. (We now have a bile-acid salt of soda.) This solution is to be evaporated to dryness; residue to be extracted with absolute alcohol. (This takes up the bile-acid salt of soda, leaving the lead behind.) Filter. Precipitate filtrate with excess of ether; allow to stand; pour off supernatant fluid; dissolve precipitate in water, and apply Pettenkofer. Much care is needed in this; for some lead follows on closely throughout."

their tendency must be pernicious. Where there is permanent obstruction, calomel is, for the same reason, interdicted. On the other hand, the removal of the elements of bile by organs supplementally acting should be encouraged. Such organs are the kidneys and the skin. Diuretics and diaphoretics are therefore indicated, and particularly such diuretics as would improve the condition of the blood at the same time. One of these is the solution of acetate of iron in the form of the so-called Basham's mixture.* The ordinary sweet spirit of nitre is a useful adjuvant tending to the skin. A remedy having considerable reputation in all cases of jaundice is nitro-muriatic acid. Its precise mode of action upon the liver is not determined. Niemeyer suggests that it may excite the muscular coat of the bile-ducts to contraction, rather than increase the activity of the liver-cells. Whatever its mode of action upon the liver may be, it is unquestionably an excellent tonic and improver of digestion. Akin to this is the fluid extract of taraxacum. And these remedies in connection with quin. sulph., gr. ij, four times a day, and easily assimilated food,—milk, beef-essence, etc.,—have constituted the treatment of our patient, under which he has greatly improved. He has been taking the acid and taraxacum in the following prescription:

℞ Ac. nit. mur., gtt. cxxviij;
Fld. ext. tarax., fℨiss;
Tr. hyoscyam., fℨss. M.
S.—Teaspoonful three times a day.

The hyoscyamus, fulfilling no special indication, will be omitted from this date, but the acid will be continued in diminished doses (minims x of the dilute preparation with fℨj of the fluid extract of taraxacum), while the nitro-muriatic acid will also be used externally in a foot-bath (fℨss to a bath). His bowels, the discharges from which continue ashen-hued, are kept sufficiently open.

Calomel we will eschew, although he received this drug soon after admission; but this was before his case was thoroughly studied. On admission he also received a dose of castor oil, followed by pills of opium and acetate of lead until his bowels were brought under control.

CONCLUSION.

While this lecture was being printed, the patient upon whose case it was based died; death having been preceded for ten days by a gradually increasing mental hebetude.

Post-mortem Examination, June 25, 1873, twelve hours after death.—Emaciation marked, though not excessive. Connective tissue throughout yellow with bile-pigment, even in the tissue of the lungs, bowels, and peritoneum. The serous fluids were similarly tinged.

Thorax.—There were no adhesions, and the lungs were normal. The heart was also healthy.

Abdomen.—The liver was adherent to the under surface of the diaphragm for a short distance on each side of the normal line of attachment by the suspensory ligament; it was also adherent to the stomach and duodenum, and in separating these adhesions with the finger the latter suddenly penetrated the gall-bladder, from which immediately ran at least twelve ounces of an apparent mixture of blood and bile. Further examination showed the upper boundary of the gall-bladder to be the parenchyma of the liver; that is, the membranous wall of the gall-bladder and the capsule of the liver seemed to be altogether wanting, the cavity of the gall-bladder being as it were an excavation in the structure of the liver, but bounded on its under surface by the proper membranous wall of the gall-bladder, which was much attenuated. Into this cavity opened two large canals of such a diameter as easily to admit the finger,—either large blood-vessels or dilated gall-ducts.

On passing a probe through the common duct it met with decided resistance at a point an inch in advance of the union of the hepatic duct with the cystic duct. To the external touch the hardness suggested a gall-stone about four lines in diameter, but on section it was found to be a cylindrical fibrinous mould of the canal, six lines in length, and in diameter sufficient completely to occlude the duct and prevent the egress of bile from the gall-bladder. Beyond this point, both the hepatic duct and the cystic duct appeared to become flattened, shreddy masses, and could not be traced into the gall-bladder, into which therefore apparently the bile was admitted directly from the liver, the ducts of which were distended and filled with bile throughout. A singular and interesting feature was a distention of the common duct between the point of its opening into the duodenum and the point of obstruction. This could only be accounted for on the supposition that there was also obstruction at this point, and that the secretion of the pancreas which is normally poured out of the same orifice was backed into the common duct as far as the point of obstruction, producing dilatation. That such obstruction at the orifice of entrance into the duodenum should exist is not unlikely, though I regret to say it was not carefully examined, the dilatation not being discovered until the liver and common duct, with a portion of the pancreas, had been removed from the body.

The liver itself weighed 3 lbs. 11 oz. (normal weight 1 lb. 8 oz. to 4 lbs.), and was increased in its vertical diameter, but diminished in its lateral, so that its cubic contents were perhaps about those of a normal organ. It was, however, congested and cirrhotic, and the gall-ducts everywhere distended with bile.

The spleen was enlarged, contained also an excess of fibrous tissue, and weighed 17 oz.

The pancreas was stained with bile, but apparently healthy.

ICE IN THE RECTUM IN THE TREATMENT OF NARCOSIS OF CHLOROFORM (*Bulletin Générale Thérapeutique*, April 15, 1873).—According to Dr. Baillée, there is no more energetic means of overcoming the narcosis produced by chloroform than the introduction of a small piece of ice into the rectum. It can be pushed through the sphincter without the employment of much force. It immediately melts, producing a deep inspiration, which is the precursor of natural respiration and the re-establishment of cardiac functions. He recommends the same plan to be pursued in cases of apparent death in new-born infants.

POST-PARTUM HEMORRHAGE.—A correspondent of the *Lancet* (May 24) details a case of profuse post-partum hemorrhage which was arrested at almost the last hour by the injection into the uterine cavity of a solution of tannin, containing four drachms to the pint of water.

NOTES OF HOSPITAL PRACTICE.

[Although these cases of Dr. Atlee occurred in private practice, yet the most appropriate place for their record seems to be under "Notes of Hospital Practice." The reports will be regularly continued.]

CASES OF OVARIOTOMY.

BY WASHINGTON L. ATLEE, M.D.,
Of Philadelphia.
Reported by J. Ewing Mears, M.D., of Philadelphia.

CASE 238.—Multilocular ovarian tumor, tapped six times; extensive parietal and omental adhesions; incision five inches in length; death on the eighth day.

June 7, 1871, Dr. Atlee visited Mrs. G., of Brooklyn, in consultation with Dr. W. K. Brown. She was 55 years old. Menstruation commenced at the age of fifteen, and was regular, painful, not profuse, and lasted four days. She was married at the age of twenty-two, had eight children, nursed them eighteen months, and had free lactation. Menstruation was suspended during lactation. The menses ceased at the age of forty-eight.
